The Dell group then sought to model the data from 21 aphasic patients who performed the same picture naming task. These patients included a variety of fluent aphasic types (Wernicke's, anomics, conduction, and transcortical sensory). To simulate the data from aphasic namers, they concentrated on two parameters of the model: p and q . Reducing the setting of p (weakening connections) or raising the setting of q (increasing decay) both cause the model to make more errors. Activation levels get small and noise has a greater influence. At moderately deviant settings of p or q , the model is correct on about 20–80% of trials. At more deviant settings the model's performance is completely dominated by noise, which means that the output consists primarily of the high opportunity errors (neologisms, unrelateds, and, to some extent, formals). This was also true in the data: neologisms, formals, and unrelateds increase as correctness decreases, but semantic and mixed errors do not. The model explains this fact in terms of opportunities for errors and the increasing role this plays as severity increases.

The combination of variation in severity and type of lesion (p or q) allows the model to simulate dissociations between patients who produce mostly semantic errors and those whose errors are mostly phonological. In the model, reduced connection strength (p lesion) diminishes the extent to which different levels of representation are consistent with one another. This promotes what the Dell group called "stupid" errors: nonwords and unrelated word errors. In contrast, q lesions promote "smart errors": semantic, mixed, and formal. Decay lesions that are not severe lead to patterns in which nearly all errors have a semantic component. Severe lesions in connection weight (p) produce a mostly phonological pattern. Combinations of p and q lesions produce intermediate patterns.

To model patient data, Dell and colleagues chose the best matching values of p and q for each patient. Table 64.2 shows the fits for three modeled patients, two who perform at the same level of correctness, but with different error patterns (L.H. and I.G.), and an additional patient whose naming is more severely disrupted (G.L.). I.G.'s primarily semantic pattern (9% semantic; 2% neologism) was closely fit by a pure decay lesion. L.H.'s more phonological pattern (3% semantic; 15% neologism) was closely fit by a pure strength lesion. G.L.'s pattern illustrates the tendency for the more severe patients to have more errors in categories with large numbers of error opportunities and the model's ability to fit that pattern. Across all 21 patients, the fit between the model and patients was good, and much better than the fit for error patterns generated at random. This is important, because it shows that there are many response patterns that cannot be simulated well by varying p and q .

The Dell group presented other evidence to support the model's characterization of the patients. For example, several patients were modeled again at a later date, when their level of correctness on the PNT had improved; and the fits were, once again, good. More importantly, the model's account of a given patient remained constant over time: If the naming profile at time 1 was best fit by a decay lesion, so too was the profile at time 2. Where substantial improvement had occurred between time 1 and time 2, this was reflected in the movement of the affected parameter closer to the normal value. This demonstrates that the original characterization of the deficit was reliable and stable. It also supports a restitution account of recovery over a compensation account: Recovery is the movement of pathological parameters toward normal values.

The DSMSG model represents the first effort to model both normal language data and data sets from a large number of individual aphasic patients (see Bates

TABLE 64.2
PNT naming data and predictions of the model

Patient Parameters	Response Types						RMSD*
	Correct	Semantic	Formal	Nonword	Mixed	Unrelated

*RMSD is the root mean square deviation between the six patient and model proportions.

et al., 1991; Plaut et al., 1996, for other attempts to model individuals). In doing so, it casts new light on some long-standing issues. On the question of the relation between normal and aphasic speech, for example, the work of Dell and colleagues, like that of Haarmann and colleagues (1997), suggests that aphasic error patterns reflect deviant values of parameters of the normal system. And it assigns new importance to the severity dimension by linking the errors of more severe patients to the opportunities afforded by the structure of the lexicon.

The parameters manipulated in the model are not specific to semantic nodes or phonologic nodes; that is, Dell and colleagues hypothesize global rather than local deficits. Nevertheless, at particular values of these parameters, the model can achieve selective promotion of one type of error over another. This raises the question of whether it is ever necessary to postulate local impairments to semantic or phonologic nodes or connections. At this point, one would have to answer yes. First, such local impairments still provide the best account for certain consistencies in performance patterns across tasks (e.g., Caramazza, 1988). Furthermore, the DSMSG model cannot handle certain pure naming error patterns, and there is evidence that such patterns do exist. For example, there are patients exhibiting low levels of correctness with purely semantic errors (Caramazza and Hillis, 1990; Hillis and Caramazza, 1995; Hillis et al., 1990) or purely phonological errors (Caplan, Vanier, and Baker, 1986). Based on these lines of evidence, it may be necessary to reconsider the model's globality as-

sumption in the model, that is, the notion that parameter alterations affect all layers of the network equally.

Apart from this, the most serious weaknesses in the model have to do with its simplicity. In its present form, the model cannot deal with the precise character of phonological errors (e.g., how target and error overlap in phonemic content and metrical and syllabic structure), or with the influence of word length and frequency, or with perseverated responses and "no response" trials. It also makes no allowance for variations in response time. Dealing with these issues will require considerable expansion of the model, both with respect to its vocabulary and to its representational and processing assumptions. It remains to be seen whether the model's fundamental assumptions about constrained interactivity within a two-step retrieval process can survive these modifications.

A parallel distributed processing approach to deep dyslexia

There can be little doubt that PDP approaches have been increasingly influential in cognitive neuropsychology (see, e.g., Farah, 1994). However, for various reasons, PDP models of language pathology have addressed single-word reading rather than spoken language production and comprehension. Consequently, these models are more properly described as models of dyslexia than aphasia. Here, we present some of the facts associated with a particular dyslexia symptom complex, deep dyslexia; then we discuss the PDP framework generally and illustrate its application to this

disorder by presenting a specific model (Plaut and Shallice, 1993).

As with other acquired dyslexias, deep dyslexia is characterized by the nature of the patients' errors when reading aloud (e.g., Coltheart, Patterson, and Marshall, 1980; Marshall and Newcombe, 1966). The defining error for deep dyslexia is the semantic error. A patient reads NIGHT as "sleep" or BLOWING as "wind." (All examples are taken from Plaut and Shallice, 1993.) In addition to semantic errors, patients also make visual errors ("sandals" for SCANDAL), and the visual and semantic influences on errors sometimes combine as in mixed visual-semantic errors (SHIRT—"skirt") or visual-then-semantic errors (SYMPATHY—"orchestra"). In addition to these error types, deep dyslexia is associated with difficulty in reading function words, verbs, and, in general, words that are low in concreteness. Reading nonwords aloud is particularly hard for these patients.

This combination of symptoms presents a theoretical puzzle. What functional system is damaged? The occurrence of both semantic and visual errors suggests different kinds of damage in the mapping from orthography to meaning. At the same time, the inability to read nonwords must reflect trouble in visual to phonological mappings. Adding to the mix are the interactions among visual and semantic errors, and the effects of concreteness. Finally, there is considerable variability among patients. For example, not all of the patients who make semantic errors make visual errors. In sum, it is a challenge to come up with a theory of deep dyslexia that follows naturally from a functional analysis of reading and does not resort to unmotivated assumptions (e.g., assuming that there are several deficits that happen to co-occur for random or unspecified anatomical reasons). Providing such a theory was the goal of Plaut and Shallice (1993), whose work we present here. However, before we turn directly to their model, it is useful to review some principles of PDP models and how they might be used in neuropsychology.

Parallel distributed processing is a framework—that is, a set of pretheoretical assumptions about what theories should be like—rather than a theory. As with the other computational approaches described here, the PDP framework assumes that processing occurs through spreading activation among simple units in a network. In contrast to the other approaches, however, the units are quite neuron-like. Each unit's activation level is a nonlinear—typically sigmoidal—function of its input. This input is the sum of signals sent from neighboring activated units through weighted excitatory or inhibitory connections. Critically, these weights are set by training the network in the mapping required for the task. In the

case of reading and reading aloud, orthographic representations need to be mapped to representations of meaning and phonology. So, a PDP reading model would be trained by presenting words to the network, one at a time, each word corresponding to patterns of activation in an input orthographic layer, and in output (semantic or phonological) layers. Connection weights would then be altered by a learning algorithm (e.g., backpropagation; see Rumelhart, Hinton, and Williams, 1986) with the effect that later presentation of that word's orthography would be more likely to produce the correct output semantic or phonological patterns.

The PDP framework's emphasis on learning the connection weights has two important consequences. First, the learning techniques that are employed develop distributed representations. In a reading model, for example, each word comes to be associated with a great many units and connections. Damage to the network—loss of units and connections, or noise added to connections—does not, therefore, necessarily lead to all-or-none loss of particular words. Performance is, instead, graded. A particular word might be correctly read under some circumstances, and incorrectly under other circumstances. Moreover, incorrect responses would be expected to resemble correct ones to varying extents. Because language pathology exhibits exactly this kind of graded performance, distributed representations have much to recommend them as accounts of aphasia and dyslexia. Another key aspect of distributed representations is that units and connections are shared among similar words. So, in a model of dyslexia, damage to a single unit or connection has ramifications for the processing of several similar words. By varying the number and location of damaged components, one can create losses of varying degrees of specificity within the vocabulary, offering a potential account of category specific losses in patients (e.g., Hinton and Shallice, 1991). In addition, if a model allows for interaction among the processing layers (which Plaut and Shallice's model does), there is the potential that damage at one layer (e.g., a semantic layer in a reading model) will create effects that reflect knowledge from other layers (e.g., visual errors; Hinton and Shallice, 1991).

The second consequence of the PDP framework's learning assumption is that learning, damage, and recovery can be understood as different manifestations of the same process (Plaut, 1996). Learning is adaptive weight change; damage is counteradaptive change to those weights; and recovery, insofar as it occurs, is relearning or further adaptive weight change. This potential to offer a theory of recovery and loss of function is a great strength of the PDP approach to neuropsychological deficits.

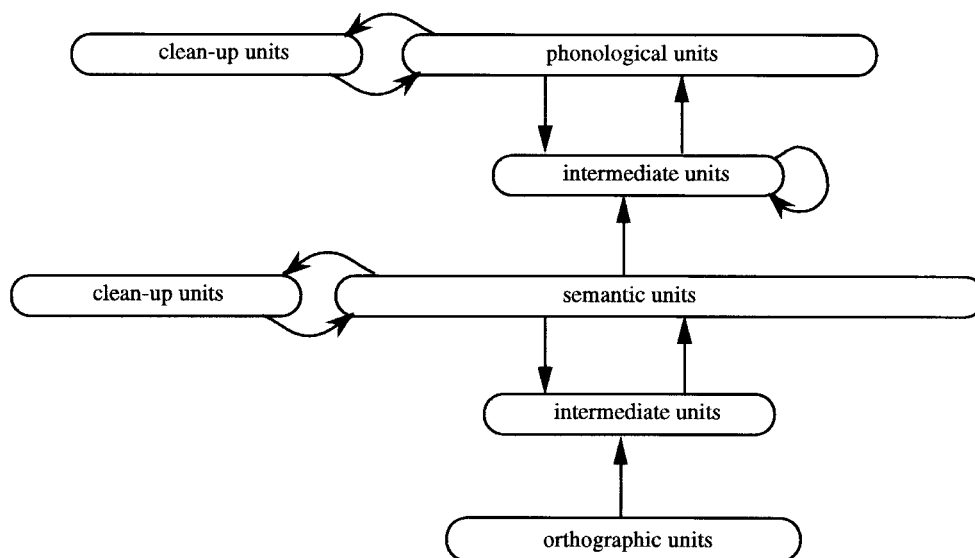

FIGURE 64.5 Architecture of a deep dyslexia model. (Redrawn from Plaut and Shallice, 1993.)

In general, the PDP framework gives the neuropsychologist a different perspective on the functional modularity of cognitive systems, and on the relation between functional modules, error types, and the actual location of damage (Farah, 1994). PDP models certainly look a lot different from the standard box-and-arrow diagrams. However, we agree with Plaut and Shallice (1993) that one should not view these models as strict alternatives to box-and-arrow models, but rather as an “elaboration” (p. 383) of them, one that identifies the computations associated with each box and each arrow more fully.

Plaut and Shallice (1993) actually implemented several models of dyslexia. Starting with a related model by Hinton and Shallice (1991), they systematically varied model characteristics including the model’s architecture (i.e., what particular levels of representation and connections are assumed), its learning algorithm, and the reading task (whether the model must assign meanings to words, or must also be capable of producing their phonological forms). In general, the models exhibited roughly similar behavior, and so we describe just one of them, the final one presented.

Figure 64.5 presents the architecture of the model. The network’s task is to generate the semantics of a word from orthographic input, and to generate the phonological representation corresponding to that semantics. In short, the network must understand a word and then pronounce it. Notice that this model is not allowing for any direct mapping from orthography to phonology, in keeping with most theorists’ view that deep dyslexics are unable to use phonology in reading for meaning.

(The absence of this mapping in the network enables it to simulate the patients’ near total failure in reading non-words.) There were three network levels with explicit a priori representations: orthographic, semantic, and phonological. The orthographic input layer contained 32 units, 8 for each of four letter positions. Each letter corresponded to a pattern of activation (1s and 0s) across the 8 units in each position. At the semantic level, there were 98 units, each representing a feature such as “hard” or “has-legs.” Crucially, concrete words (e.g., COAT) had more features (18.2) than abstract words (e.g., PLAN; 4.7 features). The phonological level used localist representations of phonemes associated with slots similar to the DSMSG model. The other layers of units shown in the figure were not associated with any a priori representation. Instead they developed through learning. Intermediate units mapped from one explicit representation to another and clean-up units mapped from explicit representations to themselves.

Each arrow in the figure indicates connections that are learned. Initially, the network was trained to generate the semantics for each orthographic word, and then later to create the phonology from the semantic patterns. The learning algorithm was backpropagation, which is a technique for training networks to generate target patterns at certain layers (here, semantics and phonology) by changing weights in response to error feedback. A critical feature of the model is that the flow of activation is recurrent or interactive. Like the DSMSG model, activation at later levels can influence earlier ones. Also, in the dyslexia model, levels feed to themselves either directly or through clean-up units.

FIGURE 64.6 How damage at the semantic level can cause visual errors. Ovals are attractor basins, and the larger dotted

oval represents a basin after damage. (Redrawn from Plaut and Shallice, 1993.)

The recurrent connections in the model allow it to develop *attractors*. To understand this concept, one must first conceive of model layers such as the semantic or phonological layer as multidimensional spaces. Each unit's activation is a dimension in this space, and hence a pattern of activation corresponds to a point in the space. When a word is presented to the orthographic level, activation spreads through intermediate units to the semantic level. The initial pattern of activation at the semantic level—a point in semantic space—then changes over time as activation circulates among the semantic, intermediate, and clean-up units. Eventually, the activation stops changing or settles, and it is this meaning that is assigned to the word. After training, familiar meanings correspond to settling points or attractors in semantic space. Points corresponding to unfamiliar meanings will tend to move to the nearest familiar meaning, defining *attractor basins*. For example, suppose that the meaning of CAT is (*feline, pet, furry, animal*). When CAT is presented to the model, the initial activation pattern might be (*feline, pet, animal, nonfurry*). However, because the model knows of no nonfurry felines, the activation quickly goes to the CAT-meaning attractor by switching nonfurry to furry. The phonological level has analogous attractor basins, ones that direct phonological output to familiar pronunciations.

The model's ability to simulate the co-occurrence of error types in deep dyslexia comes from its use of attractors. Plaut and Shallice lesioned their model by randomly removing varying percentages of connections (5–70%) in particular network locations, with the result that the model then produced errors. All of the

lesion locations, except for one that produced few errors, were associated with the basic error types in deep dyslexia: semantic, visual, mixed-visual-semantic, and unrelated errors (including some visual-then-semantic). Let us first consider the striking finding that lesions in the semantic areas produce visual as well as semantic errors.

Connectionist learning models generally find it difficult to learn arbitrary mappings, such as the relation between a word's orthography and its meaning. It is more natural for a model to want to map similar inputs, such as CAT and COT, onto similar outputs. However, because CAT and COT are unrelated in meaning, this is not possible. The potential to develop attractors in these models alleviates the difficulty. Figure 64.6 (derived from Hinton and Shallice, 1991; Plaut and Shallice, 1993) shows how this happens. As a word is read, its initial semantic representation, which is determined by the bottom-up connections only, is somewhat off of the correct one. The deviation reflects a tendency for the model to make initial semantic representations of visually similar words be similar. So, CAT's and COT's initial semantic representations would be close. However, CAT and COT exist in different attractor basins; thus, once the recurrent feedback and clean-up connections begin influencing the pattern, the semantic patterns for CAT and COT drift to their correct attractors. In short, the model learns to build large attractors in semantic space and to exploit them to simplify the initial mapping from the orthography to the semantics as much as possible. Given this mechanism, it is easy to see how both semantic and visual errors happen when the network is damaged. Dam-

age changes the attractor basins. If the attractor basin for COT changes to include that for the semantic neighbor, BED, one gets semantic errors. Other changes, particularly those at the edge of a basin far from the attractor point itself, can lead to visual errors. This is illustrated in figure 64.6, which shows how, after damage, the basin for COT expands to include the visual neighbor CAT. Because all of the lesion locations are associated with roughly the same kinds of errors, one also gets semantic errors when there is damage to visual levels. In general, the similarity of error patterns across lesion locations reflects the interactive nature of the model: The activation pattern at a particular level is influenced by that of many other levels.

Plaut and Shallice also showed that their model mimicked patients by producing combinations of visual and semantic influences on errors. For example, it made mixed visual-semantic errors. The rates of these errors for abstract words were at least three times greater than what the rate would be if semantic and visual effects were independent, for all lesion locations. So, like the DSMSG model, there is a true mixed error effect. In the deep dyslexia model, it arises because attractors are sensitive to both semantic and visual information. Words that are similar in both respects, such as RAT and CAT, would have basins that are especially close. The model also produced visual-then-semantic errors, such as PLAN→(flan)→“tart.” These occur when the semantics of FLAN is present at the semantic level (a visual error), but because the FLAN pattern is corrupted, it is subject to error when it is transmitted to the phonological level for output.

Aside from the basic types of reading errors, the model also exhibited the effects of concreteness shown by some deep dyslexic patients. Because concrete words have a richer semantics, some of the lesion types, those involving direct (e.g., orthography-to-intermediate) rather than recurrent pathways, lead to better performance with concrete words. Importantly, the model produced a key interaction found in the patients: Abstract words are associated with visual errors (41.4% of errors are visual and 6.4% are semantic) while concrete words have a higher proportion of semantic errors (36.4% visual and 32.3% semantic). The richer semantics of concrete words allows them to benefit more from constraints among the semantic features (via connections to and from the semantic clean-up units). Consequently, damage to direct pathways from orthography to semantics has a more deleterious effect on abstract than concrete words.

In general, Plaut and Shallice’s deep dyslexia model provides a compelling account of the error pattern in deep dyslexia, one that allows us to understand how

these patterns arise through learning in neural systems. Like the other models we have presented, however, it has its limitations. Because PDP models learn, their behavior must reflect the set of trained items. The deep dyslexia models—and PDP models of linguistic processes in general—use a small number of words and employ particular assumptions about their semantics. This leads to two kinds of limitations. First, the actual vocabularies used by Plaut and Shallice prohibited investigation of other aspects of deep dyslexia such as patients’ difficulties with certain syntactic classes and their morphological errors. However, a more fully developed model might accommodate these findings through the mechanisms responsible for concreteness and mixed error effects. The second limitation is that the model is not able to provide quantitatively accurate accounts of the error patterns of individual patients. Although it is possible to attribute this to characteristics of the training set and other convenience assumptions, such an attribution requires a solid understanding of the distinction between the implemented models and the theory. Such understanding is difficult to achieve within the PDP framework (or other computational modeling frameworks for that matter). The patients that would be the most difficult for the model to fit would be those whose reading errors are overwhelmingly semantic (e.g., Caramazza and Hillis, 1990). The model’s basic nature is to create both visual and semantic errors. In this way, the deep dyslexia model shares a failing with the DSMSG model.

Some comparisons among the models

The three models that we have discussed share key features. Each processes information by spreading activation and attributes pathological symptoms to quantitative variation in the mechanisms that shape activation patterns. Each offers a simple way to lesion the model, and the complexities of pathological language emerge from the processes that underlie normal performance. That is, the lesions really just exaggerate tendencies that were there to begin with. In the HJC model, aphasics’ difficulties with passives and three-argument sentences are rooted in the way that these sentences are normally understood. For the DSMSG model, aphasic naming errors patterns represent intermediate states between the normal error pattern and a completely random pattern determined by the opportunities afforded by the lexicon. Plaut and Shallice’s reading model develops a landscape of attractor basins based on visual, semantic, and phonological properties of words; dyslexic errors result from perturbations of this landscape.

Despite these similarities, the three modeling efforts contrast in several ways. Importantly, each has a different view of what brain damage corresponds to. To a large extent, the theory of damage derives from the basic architecture of the model. For the HJC architecture, which was initially developed to explain individual differences in sentence processing and working memory, it is only natural to extend the hypothesized mechanism for individual differences—capacity limitations—to aphasia. The resulting model effectively links these research areas. The damage mechanism in the DSMSG model—altering spreading activation parameters—is, in part, dictated by its localist connectionist architecture. The alternative of removing units and connections would simply lead to the wrong behavior. Patients would never be able to say some words and always be able to say others. The PDP architecture does not have this limitation. Because representations are distributed, lesions involving the removal of units and connections lead to graded, probabilistic performance. These lesions are more biologically realistic, and thus PDP models offer more potential for links to neural processes than the other architectures.

Another important difference among the models concerns the target data. Dell and colleagues sought to match individual patient data, while the Haarmann group and Plaut and Shallice were modeling general syndromes rather than patients. This distinction echoes a major controversy in neuropsychology: Should one focus on single cases or do studies comparing groups of patients in different diagnostic categories? Ideally, a model should both be able to explain the individual variation and lead to theoretically motivated grouping of patients.

Conclusions

Aphasiology as a branch of cognitive neuroscience has relied heavily on the study of unusual cases—patients who exhibit relatively pure functional dissociations. Comparison among such patients has played an important role in identifying the structure of the language processing system. Now, with the advent of computational models, the relevance of aphasia to cognitive neuroscience has broadened. In addition to providing more specific descriptions of the “boxes and arrows,” the models allow us to explain the graceful degradation (and even recovery) of performance after brain damage, and the variation among patients and between patients and normals.

Despite these accomplishments, computational models of aphasia have a long way to go. Each model has the specific limitations that we mentioned in their ability to explain the output error performance of patients. To this, we would add that the models, as currently developed,

do not relate themselves to the temporal dynamics of processing leading up to the output. They have not, for example, been applied to response time (e.g., Levelt, Roelofs, and Meyer, 1999) or event-related potential data (e.g., Swaab, Brown, and Hagoort, 1997).

In addition to the models’ empirical limitations, the theories behind the existing models are seriously underdeveloped in two respects. First, there is the problem of meaning. Language is a mapping between utterances and meanings. We have some solid ideas about the units and structures of utterances, and the existing models make good use of this knowledge. However, our understanding of the semantic representations of words and sentences is less fully developed, and consequently the models have less to work with. The models dealing with words use somewhat arbitrary representations of features to represent word meaning. The sentence processing model assigns each word a core meaning, which is activated when the word is processed. But these representations are not decomposed into features, and there is no provision for shifting meaning as a function of context. While new meanings are created when the thematic role component binds noun arguments to a verb, these representations simply consist of the specified roles (e.g., agent) and the noun fillers, along with the verb. So, for example, in figure 64.1, assigning GIRL the role of KICKER does not alter the representation of GIRL. Until we gain a better understanding of semantic representations, computational modeling of aphasia will be severely hampered.

The second undeveloped area concerns the models’ ties to the brain. One reason that aphasia is of interest is that it allows for inferences about the brain-behavior mapping for language. At present, computational models of aphasia have had little to say about this mapping, aside from statements that link the model as a whole to well-known language areas (e.g., left posterior language regions for the DSMSG model). This, we expect, will soon change. Not only will the models be used to interpret functional imaging and lesion location data, but they ultimately will be able to make predictions about such data. If a model provides an effective functional explanation of language behavior, which the models that we have discussed here are beginning to do, there is no reason why it should not offer insight into neural mechanisms.

NOTE

1. In both (1c) and (1d), generative grammar postulates the movement of noun arguments from their base positions in the sentence, such that processing involves linkage of the argument to a trace inserted at the moved location. Some investigators have suggested that traces are a source of difficulty for aphasics (e.g., Grodzinsky, 1990).

65 The Neural Architecture of Language Disorders

NINA F. DRONKERS, BRENDA B. REDFERN, AND ROBERT T. KNIGHT

ABSTRACT Traditional models of language processing in the brain presume certain functions for Broca's area, Wernicke's area, and the fiber tracts that connect them. These descriptions have served a useful clinical purpose over the last century, but recent advances in the study of language and in structural and functional neuroimaging have found them somewhat insufficient. This chapter discusses findings from our work with aphasic patients examining the relationship between specific speech and language disorders and the lesions underlying these deficits. It is shown that traditional language areas may serve somewhat different functions than originally described, and that the identification of more specific deficits and their neuroanatomic correlates can lead to more informative mapping of language functions in the brain.

Much has been written about the behavioral deficits observed in the various types of aphasia, or language disorders, that arise from injury to the brain. Some describe the clinical manifestations of the disorders, others, the implications for theories of normal language processing. In this chapter, we discuss the brain areas that have been associated with these disorders and the current neurological model of language processing that was derived from these patient studies. We begin with a review of the clinical observations of Broca and Wernicke—observations that laid the foundation for how most clinicians and neuroscientists believe the brain processes language. We provide some basic information about the three aphasias that are most pertinent to this model and show how these descriptions have changed since they were first presented more than 100 years ago. Finally, we present our view of the organization of language in the brain by reviewing what we have learned from our patients with aphasia. We review the speech and language deficits we have studied and the correlations we have found with the brain areas that were destroyed by these patients' injuries. With these more recent data, we hope to provide some suggestions for expanding current models concerning the neural architecture of language disorders.

ROBERT T. KNIGHT University of California, Berkeley, Calif.

The classical theory

In the late 1700s, the simple observation of a 14-year-old formed the basis of a theory concerning the neural mechanisms of language. At that time, Franz Joseph Gall noticed that some of his more articulate friends also had markedly protruding eyeballs. He reasoned that the areas of the brain behind both eyes must have grown larger to accommodate the superior language skills of his friends and were thus pushing the eyeballs forward. With this, Gall instigated the popular practice of phrenology in which bumps on the head were related to enhanced "faculties" of the mind. Even after the phrenology fervor had subsided, many scholarly societies still debated whether speech resided in the frontal lobes.

It was in this context that (Pierre) Paul Broca, a surgeon with an interest in anthropology, saw a patient with an infected leg and a right hemiparesis who also had lost the capability of speech. The patient, whose name was Leborgne, could only utter the single syllable, "tan," which he used each time he initiated speech. Broca thought the patient understood most of what was said to him and thus presented as the perfect case to prove Gall's theory of speech in the frontal lobes. As it happened, the patient died a few days later and Broca was able to view the brain at autopsy. Indeed, a lesion was found in the frontal lobe on the posterior surface of the third frontal gyrus on the left side (Broca, 1861), the area later referred to as "Broca's area" (figure 65.1). Broca also noted softening as far posterior as the parietal operculum; but since he was only looking for involvement of the frontal lobes, this observation was deemed less important. In order to preserve the brain for posterity, it was never cut, and the extent of the lesion medially or posteriorly was not known until a century later (Signoret et al., 1984). By that time, the notion that the frontal lobes were involved in speech was firmly set.

Broca believed that Leborgne's deficits affected only his articulation abilities, not his language; hence he termed the deficit "aphemia," not "aphasia." Later, he published another, very similar case, also with a right

FIGURE 65.1 Lateral view of the left hemisphere with some of the brain areas implicated in language labeled in boldface.

hemiparesis and a lesion in the left frontal lobe. Two years later, he had accumulated six more cases, none of which came to autopsy, but all of which had a right hemiparesis. By 1865, Broca realized that the co-occurrence of the right hemiparesis and the speech deficit was beyond coincidental and concluded that it was the *left* frontal lobe, at least in right-handers, that controlled the ability for speech.

Not long thereafter, Carl Wernicke, a 26-year-old physician, described another type of language problem. He had examined two patients with profound deficits in understanding spoken language. Their speech, though perfectly fluent, was incomprehensible and riddled with nonsense words that did not exist in German. Wernicke examined the brain of one of these patients and found a lesion in the posterior part of the superior temporal gyrus, posterior to primary auditory cortex (figure 65.1). The lesion of the other patient was assumed to be in the same place. He associated this region (later termed “Wernicke’s area”) with the storage of “the auditory memory for words.” Wernicke believed that comprehension deficits were caused by the loss of these memories, while the distorted output was due to the inability to monitor self-spoken auditory images (Wernicke, 1874).

By documenting this second type of language disorder, Wernicke provided a formal distinction between two components of language, firmly departing from previous phrenological notions that language was a single entity, localizable in one brain region. With the addition of this new aphasia, differences were drawn between the “expressive” aphasia of Broca and the “receptive” aphasia described by Wernicke. Though these terms are now considered somewhat imprecise, the differentiation was an important one for its time and set aphasiologists to

thinking about what other components of the language system could be affected by brain injury.

Wernicke made another important contribution to the study of brain and language. He detailed an impressive theory establishing the notion of brain centers and the connections between them. He believed that auditory memories, first evoked in the posterior superior temporal gyrus, were then passed on to Broca’s area where they were prepared for articulation. He thereby predicted another type of aphasia, “conduction” aphasia, caused by lesions to the pathway *between* these centers, resulting in an interruption of the transmission of linguistic information from Wernicke’s area to anterior speech areas. The result would be a disruption in verbal production, since auditory word images evoked in Wernicke’s area would be cut off from articulatory mechanisms in the frontal lobe.

This “connectionist” approach, as it came to be called (not to be confused with the “connectionism” of today’s models), became extremely popular. Though it underwent a period of disfavor in later years, it returned to popularity with the work of Norman Geschwind. In his influential paper, “Disconnexion syndromes in animals and man” (Geschwind, 1965), he presented and explained several behavioral deficits in terms of the lesions in major centers and the disconnections between them. For the study of aphasia, he assimilated the most current information from behavioral neurology, psychology, and linguistics and formulated a working model of the neural mechanisms of language (see Geschwind, 1970). This model assumed the involvement of Wernicke’s area in language comprehension and that of Broca’s area for articulation and possibly in assisting in the grammatical organization of language. Geschwind also identified the arcuate fasciculus as the fiber pathway that should con-

Patient WR (Broca's aphasia)

"O, yeah. Det's a boy an' a girl ... an' ... a ... car ... house ... light po' (pole). Dog an' a ... boat. 'N det's a ... mm ... a ... coffee, an' reading. Det's a ... mm ... a ... det's a boy ... fishin'." (Elapsed time: 1 min, 30 s)

Patient OB (Wernicke's aphasia)

"Ah, yes, it's, ah ... several things. It's a girl ... uncurl ... on a boat. A dog ... 'S is another dog ... uh-oh ... long's ... on a boat. The lady, it's a young lady. An' a man. They were eatin'. 'S be place there. This ... a tree! A boat. No, this is a.... It's a house. Over in here ... a cake. An' it's, it's alot of water. Ah, all right. I think I mentioned about that boat. I noticed a boat being there. I did mention that before.... Several things down, different things down ... a bat ... a cake ... you have a...." (Elapsed time: 1 min, 20 s)

nect Wernicke's and Broca's areas as it passes through the parietal lobe. Lesions to it would presumably cause a disconnection of these two areas, resulting in the repetition deficit so characteristic of conduction aphasia, the other type of aphasia predicted by Wernicke more than a century ago.

Current descriptions of the aphasias

Current descriptions of aphasic deficits have modified Broca's and Wernicke's definitions considerably. Recall that Broca considered the deficit in his patients to be exclusively in articulation. He was confident that his patients understood everything said to them. Wernicke viewed his patients' problem as one in the storage of "the auditory memory for words." He believed that the loss of these memories resulted in the comprehension deficit, while an inability to monitor self-spoken auditory images resulted in his patients' distorted output. Today, we describe the main aphasias in a somewhat different way.

BROCA'S APHASIA The most striking characteristic of Broca's aphasia is the slow and effortful speech and the lack of grammatical markers in language production. Utterances are produced in a telegraphic or agrammatic style, with patients relying mostly on high-frequency content words and omitting the smaller function words that convey mostly grammatical information (see box 65.1.) Repetition is impaired in the same fashion as their spontaneous speech. Word-finding is also impaired and contributes to the difficulty in production.

Patients with a more severe form of Broca's aphasia can produce nothing more than recurring utterances—syllables, words, or phrases repeated again and again

(e.g., "/tono tono/," "yes, yes," "Sweet sweetie, I miss sweet sweetie")—like Leborgne's "tan." Patients with a milder Broca's aphasia tend to produce sentences and phrases that contain some grammatical organization. However, some aphasia batteries will not recognize a patient as a Broca's aphasic unless there is a complete absence of such structures in the patient's spontaneous speech.

Patients with Broca's aphasia were long thought to have intact language comprehension. This is clearly not the case. Although these patients appear to follow conversations with little difficulty, careful testing reveals that complex grammatical structures requiring the manipulation of grammatical information or the processing of grammatical rules elude them. Thus, the sentence "The boy kissed the girl" may be understood perfectly, while the more complex sentence "The girl was kissed by the boy" may not, though their meanings are identical. There is much debate as to the nature of this phenomenon—whether it is due to a central syntactic processing deficit or to an attentional or working memory disorder, and whether this deficit is associated with Broca's area. No doubt this debate will continue for years to come, as syntax is a critical part of human language, conceivably comprising the fundamental difference between our communication system and those of other species.

Speech deficits such as *dysarthria* and *apraxia of speech* frequently accompany Broca's aphasia. Dysarthria is the inability to control the muscles of articulation. Speech sounds are systematically distorted such that all of the patient's utterances sound similarly weak and flaccid or spastic, depending on the type of dysarthria. Apraxia of speech is an articulatory programming disorder that produces errors that, while inconsistent, approximate the target word (e.g., saying /yawyer/ for

“lawyer” or /chookun/ for “cushion”). These disorders also contribute to the fluency deficits of patients with Broca’s aphasia and must be distinguished from the aphasia itself.

WERNICKE’S APHASIA Patients with Wernicke’s aphasia have a deep disruption in their ability to use language to express their ideas. Whereas Broca’s aphasics can participate in a conversation and get most of its meaning, Wernicke’s aphasics can understand very little of what is said and contribute less in return. Again, there is considerable range in these characteristics, with some patients communicating some linguistic information and others producing only jargon, or meaningless sounds.

Patients with Wernicke’s aphasia score poorly on tests of auditory and reading comprehension. In severe cases, their ability to understand even single words is compromised. Comprehension of sentences and phrases is even more impaired. The spontaneous speech of Wernicke’s aphasic patients is very fluid, quite the opposite of the halting and telegraphic style of Broca’s aphasia (see box 65.1). Sentences appear to be well-formed but are often riddled with *paraphasias*, words that are substituted for the intended word. If one did not speak the patient’s language, one would be unable to detect anything particularly wrong, the speech output being so fluent. Word retrieval on confrontation naming tasks is severely impaired. Patients with Wernicke’s aphasia not only have difficulty in finding the correct word but often cannot recognize the correct name even when it is offered to them.

CONDUCTION APHASIA The hallmark of conduction aphasia is the repetition deficit in contrast to relatively preserved comprehension. Patients with conduction aphasia can repeat single words and short high-frequency sentences (e.g., “He is not coming back”) fairly easily. Longer sentences, or those that might occur less frequently in normal language (e.g., “The pastry cook was elated”), are far more difficult for conduction aphasics. In contrast, their auditory comprehension is relatively intact, even demonstrating their understanding of a sentence they were just unable to repeat.

Other aphasias include *global aphasia* (in which language is very severely impaired, yielding something of a combination of Broca’s and Wernicke’s aphasia), *anomic aphasia* (in which a word-finding problem is the most significant impairment), and the *transcortical aphasias* (in which repetition is spared). Clinically, these aphasias are seen very often, but are less relevant to our discussion and will be treated cursorily. More detailed descriptions can be found in clinical reference books such as Benson

and Ardila (1996), Goodglass (1993), and Goodglass and Kaplan (1972).

Does the classical theory explain these disorders?

Since Broca’s and Wernicke’s observations, converging evidence from several other sources has emerged to support some of their claims. For example, Broca’s important distinction between left and right hemisphere contributions to speech continued to find support through numerous lateralization studies, including those with split brain patients, and those using dichotic listening and visual half field testing. In addition, observations of aphasic patients confirmed that the aphasia of 90–98% of right-handed patients was caused by left hemisphere lesions. The work of Rasmussen and Milner (1977) also demonstrated that 95% of right-handed patients undergoing Wada testing for epilepsy surgery became temporarily aphasic after injection of the anesthetic into the left internal carotid artery feeding the left cerebral hemisphere. Furthermore, Penfield and Roberts (1959) found that electrical stimulation to the left hemisphere of the brain caused aphasia-like symptoms more often than right hemisphere stimulation.

But evidence about the localization of language and speech *within* the left hemisphere has been less well substantiated. For the most part, the classical model is successful at describing patients’ disorders and in predicting the brain areas that are compromised. However, there are numerous occasions on which the model fails. Some examples from our own clinic may help to illustrate this point.

Patient JC has a large frontal lobe lesion encompassing Broca’s area and areas anterior and superior to it, extending deep into underlying white matter (figure 65.2). Traditional theory would predict that this patient should have a Broca’s aphasia, producing short telegraphic sentences consisting mostly of high-frequency content words and few function words (prepositions, conjunctions, etc.), with impaired comprehension for complex grammatical constructions (embedded clauses, passive voice, etc.). Though JC’s speech is slow and effortful, the sentences he produces are perfectly grammatical and contain numerous examples of complex constructions. In addition, his language comprehension is virtually unaffected. Another patient, JH, does have a persisting Broca’s aphasia with the symptoms just described, but his lesion completely spares Broca’s area.

As for Wernicke’s area, patient MC has a lesion encompassing Wernicke’s area and should have impaired comprehension and a Wernicke’s aphasia. Instead, this patient has intact auditory comprehension and the repetition deficit typical of conduction aphasia. Patient OB

FIGURE 65.2 Top: Computer-reconstructed lesions of two patients, one with a lesion involving Broca's area (patient JC) and one with a lesion in Wernicke's area (patient MC). Neither of these patients was classified with the Broca's and Wernicke's

aphasia predicted by traditional theory. Bottom: Two patients who do classify with a Broca's aphasia (patient JH) and a Wernicke's aphasia (patient OB). Neither of these patients has a lesion in Broca's or Wernicke's areas, respectively.

has a dense Wernicke's aphasia with severely impaired comprehension and conversation littered with paraphasic errors. His lesion should include Wernicke's area. But it doesn't. In fact, his lesion spares Wernicke's area and instead involves the middle temporal gyrus and underlying white matter.

None of these patients is left-handed or multilingual; nor does any have an early neurological or medical problem that might have caused a reorganization of language functions in their brains. Moreover, these patients are not isolated examples. Even after Broca's historic paper, numerous cases were presented that refuted Broca's claim (e.g., Charcot cited in Finger, 1994; Bateman, 1870; Brown-Sequard, 1877; Marie, 1906; Moutier, 1908). Several found patients with lesions to Broca's area who had no Broca's aphasia at all or patients with Broca's aphasia and no lesion in Broca's area. Even the renowned neurosurgeon Wilder Penfield was reported to have completely removed Broca's area with no persisting speech or language impairments. Mohr (1976) did an extensive review of the literature on Broca's area and Broca's aphasia and found that it takes a much larger lesion than Broca described to produce a persisting Broca's aphasia. Other studies have looked at the relationship between Broca's area and Broca's aphasia and Wernicke's area and Wernicke's aphasia, with most finding a far-from-perfect correlation (e.g., Basso et al., 1985; Bogen and Bogen, 1976; Dronkers, Redfern, and Ludy, 1995; Mazzocchi and Vignolo, 1979; Murdoch et al., 1986). Why does the model fail so often?

One reason the model is often inadequate is that it oversimplifies the richness and complexity of language. Language is more than just speaking and listening; it

consists of complex rules that govern the way we combine sounds and signs into words and sentences to express thoughts to other human beings who share the same set of rules. At the very least, it involves retrieving words that label concepts, retrieving and applying the grammatical constraints that convey the relationships between the words, preparing the words for articulation, attaching the appropriate intonational patterns and social rules particular to the situation, and then producing the utterance through speech or signed gestures. The field of linguistics is entirely dedicated to studying the intricacies of this complex system, to an extent that could never have been appreciated in Broca's or Wernicke's time.

Second, many studies have attempted to localize behaviors that were not stable. It is now known that in patients with acute Broca's aphasia in the first few weeks after injury, the condition often evolves into a milder form of language impairment, where the deficit is largely one of word-finding. In patients with acute Wernicke's aphasia, the condition almost always evolves into a milder conduction aphasia or anomic aphasia. These early deficits are most likely influenced by the effects of the lesion on neighboring or connected brain regions and do not accurately reflect the deficits caused by lesions to these areas. In our opinion, this lesion-deficit correlation must wait until the behavior has stabilized.

Finally, aphasiologists have never agreed on what we are trying to localize. Broca thought it was the faculty of articulation that resided in Broca's area; later in history, it was syntax. In fact, Broca's aphasia is a *syndrome*, a cluster of aphasia deficits that collectively form a pattern. Patients with Broca's aphasia have numerous

FIGURE 65.3 This three-dimensional MRI reconstruction depicts the lesion in a patient with anomic aphasia and an apraxia of speech. The upper left image is a horizontal slice showing the left hemisphere lesion, while the upper right depicts a coronal section. (The images conform to radiologic con-

vention, with the left hemisphere shown on the right side.) In the lower left is a sagittal section through the left hemisphere. The lower right image shows the 3D reconstruction of the brain with part of the lesion visible on the lateral surface of the left hemisphere.

problems: They are impaired in articulatory agility, word-finding, repetition, and comprehension for complex grammatical structures. Realistically, it makes little sense to suppose that all of these behaviors would be located in one area of the brain. Instead, we find that looking for brain areas associated with more specific components of the speech and language process results in far more reliable correlations. We illustrate this point in the following section.

Recent contributions

Over the last several years, we have looked closely at the specific deficits in our aphasic patients and evaluated these in parallel with a careful analysis of lesion sites. Owing to the large number of aphasic patients at our fa-

cility, we have been able to impose several controls on our studies. First, all of the patients we study have suffered a single cerebral infarction (stroke) with no previous neurologic or psychiatric history that might influence their results. All are right-handed, native English-speaking, and have normal or corrected-to-normal vision and hearing. All speech and language testing is performed at least one year after the stroke to ensure that the deficits are stable and persisting. Each patient has undergone CT or MR imaging at least 3 weeks post-onset so that the boundaries of the lesion can be clearly discerned and reliably reconstructed. Most cases are imaged close to the time of testing, and on some patients, we have also obtained 3D MRIs (figure 65.3; see also color plate 43). Patients' lesions are reconstructed onto templates and entered into a microcomputer running

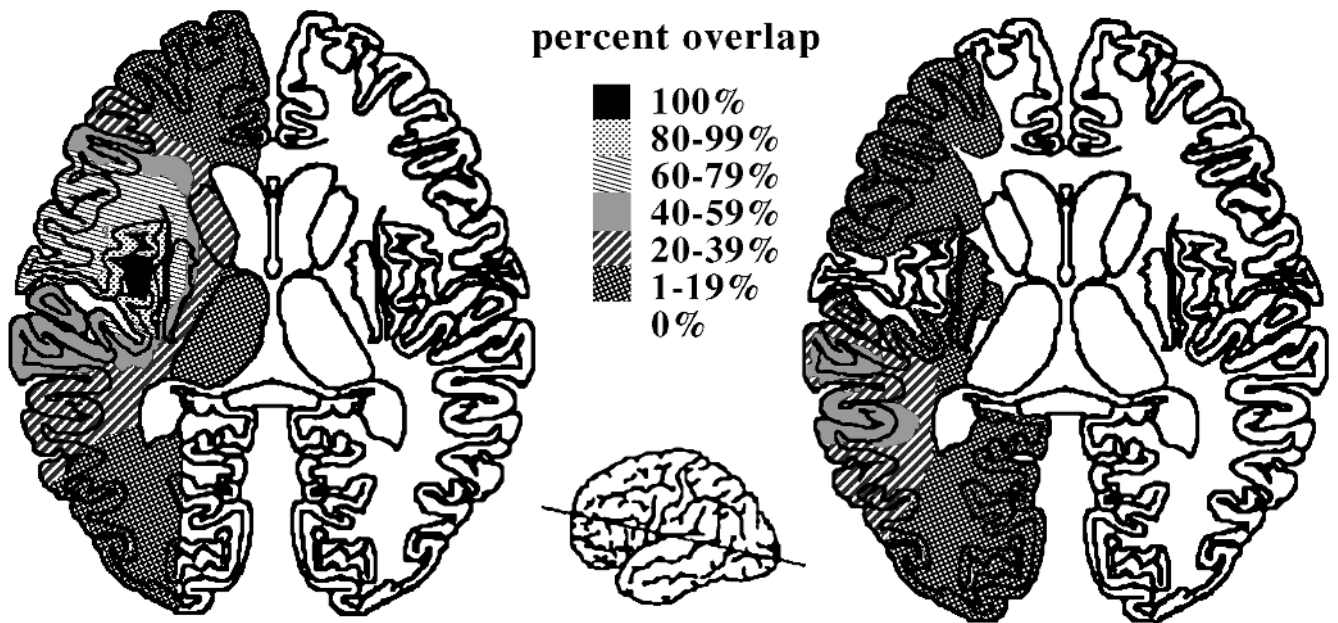

FIGURE 65.4 Lesion overlapping in 25 patients with apraxia of speech (left) and 19 patients without this disorder (right). All of the 25 patients with apraxia of speech have a lesion encom-

passing a small section of the insula, as shown in yellow, while the lesions of the 19 patients without apraxia of speech completely spare the same area.

software developed at our facility (Frey et al., 1987). Patients who exhibit similar deficits are grouped together and their lesions overlapped by the computer to reveal any common areas of infarction. In this way, lesion locations can be determined that are shared by all patients exhibiting the same disorder.

We have accumulated substantial behavioral and imaging data on more than 100 patients, each of whom met all of these criteria. In our first test of this analysis, we examined 12 right-handed chronic patients with a persisting Broca's aphasia and overlapped their lesions to see if Broca's area was involved in all cases, as predicted by traditional theory (Dronkers et al., 1992). It was not. Two cases had lesions that completely spared Broca's area, even though their aphasia was classified as Broca's with a standardized aphasia battery. In addition, we found ten other patients with lesions in Broca's area who had no Broca's aphasia at all, confirming Mohr's finding. Most of these were mildly anomie, and one was a conduction aphasic with a large posterior lesion extension. Thus, we received our first confirmation that the classical model would not be able to explain all of our patients' language deficits.

Yet the lesion overlapping of the Broca's aphasics did yield a consistent relationship. All of the patients with Broca's aphasia, even those without lesions to Broca's area, had a lesion that encompassed part of the insula, the island of cortex deep within the cerebral hemispheres. This led us to explore whether this area might

be the critical area for Broca's aphasia, much as Marie (1906) had once suggested. In fact, we found numerous patients with lesions in this area of the insula who did not have a Broca's aphasia, but did have an apraxia of speech in common. This disorder is believed to be a deficit in planning the movements necessary for speech, with patients producing inconsistent errors that are phonemically similar to the target word. We found that when we overlapped the lesions of 25 patients who were diagnosed with this disorder, all had involvement of a discrete area of the superior tip of the precentral gyrus of the insula (Dronkers, 1996; see figure 65.4). To be certain that the finding was not artifact, we also overlapped the lesions of 19 patients without apraxia of speech and found that their lesions covered nearly as large an area within the left cerebral hemisphere, but completely spared the part of the precentral gyrus that was lesioned in all of the patients with the disorder (figure 65.4; see also color plate 44). This clear dissociation led us to link this new functional area with this articulatory planning deficit.

With regard to Broca's aphasia, apraxia of speech is a disorder that nearly always occurs in patients with this type of aphasia. Thus, it is not surprising to find that the same area of the precentral gyrus of the insula that was lesioned in all of the patients with apraxia of speech was also lesioned in the patients with Broca's aphasia. Even if we overlap the lesions of patients with a milder, but still Broca-like aphasia, we find that these patients also

have lesions in the same area of the insula, and all have an apraxia of speech. Are we saying that this spot on the precentral gyrus of the insula is the new Broca's area? No. We are merely saying that apraxia of speech is one of the central deficits of patients with Broca's aphasia, and this particular behavior is likely caused by lesions to this specific area of the insula.

Another problem of Broca's aphasic patients is in sentence comprehension, particularly for complex grammatical constructions. We have found that patients with lesions to the anterior portion of the superior temporal gyrus have difficulty in processing sentences, particularly those with complex grammatical constructions (Dronkers et al., 1994). This area has rich connections to the hippocampus and may be involved in recruiting memory mechanisms that contribute to the processing of longer and more complex sentences. Other studies have also implicated this area in sentence processing with PET and fMRI technology (Bevalier et al., 1997; Mazoyer et al., 1993). Not surprisingly, this is also an area lesioned in many patients with persisting Broca's aphasia. This is not to say that this area is involved exclusively in sentence comprehension. Language processing at the sentence level is extremely complex and undoubtedly involves numerous brain regions and co-processes.

A feature of more severe Broca's aphasia is that of "recurring utterances," those phrases that are involuntarily produced each time the patient attempts to speak. Here again, we find that Broca's aphasic patients with this characteristic share a common lesion (Dronkers, Redfern, and Shapiro, 1993). Specifically, all had lesions that severed the arcuate fasciculus in a region of the brain where the fibers of this important tract bundle together and ascend out of the temporal lobe to pass over the ventricles. This fiber bundle is susceptible to injuries in the deep parietal region, as even small strokes can completely bisect it, disrupting the transmission of information generated in posterior language zones to more anterior motor speech areas. Classical theory predicts that lesions to this fiber tract would result in repetition deficits. Instead, patients with this lesion cannot speak at all, much less repeat. Aphasic patients without this lesion are not impaired in this way.

Thus we see that trying to associate Broca's aphasia to any one area is futile since this aphasia type is, in reality, a syndrome complex consisting of many different individual deficits. Instead, each specific problem may be related to particular brain areas that subserve specialized functions. The fact that it takes such a large lesion to produce a persisting Broca's aphasia tells us that this lesion must encompass several different brain areas in order to

capture all the structures involved in processing the different aspects of language that are disrupted in this syndrome.

With regard to Broca's area, we feel that a more conservative conclusion should be drawn concerning its function. Given that neurosurgical resection and other injuries to Broca's area result in only a passing motor speech deficit, it may be more reasonable to attribute a limited role specifically in articulation to this region, much as Broca himself had originally done. The location of this area, neighboring on motor face cortex in the primary motor strip, makes it a perfect candidate as a motor association area dedicated to the motor control of the speech musculature. It is likely that in our quest to associate deficits in higher linguistic functions to Broca's aphasia, we may have inadvertently assigned too great a responsibility to Broca's area. Another possibility is that it (or neighboring regions) may play a role in working memory for linguistic material (Stromswold et al., 1996) or function as part of an articulatory loop (Paulesu, Frith, and Frackowiak, 1993), as some recent PET studies have suggested.

This is also true of Wernicke's aphasia and the role we attribute to Wernicke's area. We have found that of seven patients with a persisting Wernicke's aphasia in our group of more than 100 chronic left hemisphere aphasic stroke patients, only five have lesions in Wernicke's area (Dronkers et al., 1995). Seven additional patients have lesions in Wernicke's area with no persisting Wernicke's aphasia. Others have found such discrepancies, as well (Basso et al., 1985). In fact, there is quite a bit of disagreement as to where Wernicke's area is (Bogen and Bogen, 1976), since Wernicke himself had no autopsy data on his first patient and the second patient was reportedly demented, with numerous other neuropathological findings.

We have found that, as in Broca's aphasia, it takes a larger lesion encompassing areas outside of Wernicke's area to produce a persisting Wernicke's aphasia. Most of our chronic Wernicke's aphasics have large temporal lobe lesions with total destruction of the posterior half of the middle temporal gyrus, and all have significant involvement of the underlying white matter. Patients with smaller temporal lobe lesions tend to have transient Wernicke's aphasia which resolves to a milder aphasia type within the first year of recovery. Interestingly, these smaller lesions can be anywhere within the posterior half of the temporal lobe and still produce a Wernicke-like aphasia for the first few months. Thereafter, the network of semantic information that resides in the posterior temporal lobe is apparently able to compensate for the hole in its web, with the patient recovering to a milder residual deficit.

With regard to Wernicke's area itself, we find that lesions there lead to the repetition deficits characteristic of chronic conduction aphasia (Dronkers et al., 1998) and not to a persisting Wernicke's aphasia. These patients have difficulty in holding the sentence in echoic memory and repeating these sentences verbatim, but have little difficulty in understanding the meaning of the sentence. They also have trouble deciding whether two words rhyme, particularly when orthographic or semantic cues cannot be used to make the decision (e.g., when the ends of the words do not share the same spelling or when the words are nonsense words with no meaning). Apparently, the echoic trace is lost, preventing patients from hanging onto the sounds of these words, making rhyme judgments difficult and verbatim repetitions of low-frequency phrases nearly impossible. Other work also points to the involvement of the superior temporal gyrus in the perception and immediate store of auditory information (Damasio and Damasio, 1980), while more complicated semantic processing involves larger temporal regions.

Conclusion

In sum, the earlier aphasiologists identified several key areas in the brain that they thought related to speech and language. Our analysis, with more modern tools and assessments, suggests a somewhat different role for these key areas than has been assumed over the years. Our findings indicate that Broca's area is not related to "speechlessness" as Broca claimed, nor necessarily to grammatical processing, as later psycholinguists believed. Its precise role remains to be seen, and current functional neuroimaging may help to cast some light on this issue (see Brown, Hagoort, and Kutas, this volume). Wernicke's area seems to be related more to echoic rehearsal than to "language comprehension," and the arcuate fasciculus to carrying all types of utterances forward to motor speech areas, not just those that need repeating.

Still, the observations of Broca and Wernicke have pointed us in the right direction toward understanding language and the brain. After all, Broca said the posterior inferior frontal gyrus was related to "the faculty of articulate language" and it is clear that frontal areas do contribute to speech output. Wernicke thought the posterior superior temporal gyrus responsible for language comprehension. Though there is some controversy regarding the role of that particular gyrus, it is generally accepted that the temporal lobe is critical for the storage and retrieval of words and their meanings.

In our view, temporal association cortex, in particular, the middle temporal gyrus, is the region of the brain that is most involved with the core components of language.

Lesions to this general area cause the most profound language deficits, as can be seen in our severe Wernicke's aphasic patients. These individuals demonstrate how destruction of large amounts of temporal cortex with extensive white matter damage can lead to permanent loss of important language functions and the effective use of language in both production and comprehension. Small lesions lead to temporary loss, as though the network is able to reorganize itself if the damage is not too extensive. Localization of specific functions within this temporal lobe network will most likely never be possible since it is built on individual experiences that differ from person to person.

On the other hand, there are speech and language mechanisms that are highly localizable, as our work with articulatory planning and echoic memory has indicated. It must be kept in mind that such functions represent input, output, or support mechanisms for the language system and thus would not be expected to vary greatly across individuals. The function of the arcuate fasciculus in transferring information between language areas should therefore also be consistent. The role of the anterior superior temporal gyrus in sentence comprehension also seems to be consistent across patients, but again, is most likely an area that provides support to a very complex process. Brain regions that contribute to such cognitive functions as attention, memory, working memory, and executive control certainly also play their roles in supporting the processes of language.

Finally, in evaluating the validity of the classical model, we must keep in mind how it was derived. Recall that Broca was very interested in whether Gall's idea of language in the frontal lobe could still be supported, even after other phrenological relationships were discarded. When he examined the brain of Leborgne, he was specifically looking for a lesion in the frontal lobes. When he found one, he took it as immediate confirmation of Gall's theory, even though he never cut the brain to see how extensive the damage was. In addition, Broca's patient had apparently suffered numerous strokes and it was never clear which one had led to his "speechlessness." Ironically, such a patient would never be included in today's localization studies. Broca's second patient also had a deeper frontal lobe lesion, though Broca considered only the posterior inferior frontal gyrus to be of importance. His subsequent cases were rarely autopsied, only assumed to have the same lesion.

Wernicke's cases are no more convincing by today's standards. One was demented, with widespread neuropathological changes, while the other patient recovered within weeks and was never autopsied. While many subsequent cases provided support for Broca's and

Wernicke's claims, many were also found to refute them. In fact, the Wernicke model fell out of favor for most of the century and was replaced with numerous other theories. It was not until Geschwind revived the model in the 1960s that it was again brought into vogue.

The last century has seen a blossoming of interest in the neural mechanisms of language and great changes in how these functions are investigated. New technologies and a better understanding of the behaviors we are trying to localize have merged to offer us some necessary modifications to the classical theory. The classical language areas may indeed contribute to language processing, but may do so in slightly different ways. It is also clear that other brain areas besides Broca's area, Wernicke's area, and the arcuate fasciculus can contribute to language processing. Some of these areas determined by lesion analysis include the insula, the anterior superior temporal gyrus, and a larger swath of temporal cortex than previously thought. These modifications do not belittle the older model in any way; they merely offer us the opportunity to improve upon it and to come to a better understanding of the areas involved in speech and language.

Introduction

STEPHEN M. KOSSLYN AND EDWARD E. SMITH

In this section we consider examples of cognitive abilities that are often characterized as higher brain functions, as distinct from lower brain functions. Functions like those involved in early perception and motor control are considered “lower,” while those involved in reasoning and problem solving are considered to be “higher.” Lower functions often appear to rest on a relatively small collection of processes. And these processes perform a small number of specific operations, interact in straightforward ways, and operate in the same way over a wide range of different “contents” (specific information). For example, low-level perceptual processes operate the same way whether we see a shoe being tied or watch a movie of a horse stepping on a snake. In contrast, higher functions rely on relatively large numbers of processes, and these processes may themselves have complex internal structures. Moreover, their interactions are rarely straightforward, and their operations can vary for different contents. For example, when reasoning about relative quantities, the strategies we use may depend, in part, on the actual quantities involved. Asked to multiply two single-digit numbers, we may rely on rote memorization; but if asked to multiply two double-digit numbers, we may visualize them, rehearse their names, and use various strategies to keep partial results in mind while proceeding. Higher functions are often organized hierarchically, the more complex ones drawing on collections of more fundamental (and simpler) ones. And these more complex functions may have “emergent” properties—properties that cannot be predicted based on simple interactions among simpler functions.

The characteristics of higher functions imply that such functions will be difficult to understand. In many cases, we may not *fully* understand higher cognitive

functions until we understand the more basic lower-level functions that they invoke. Nevertheless, it is erroneous to assume that we cannot begin to understand higher cognitive functions until we have understood simpler, lower-level ones. Cognitive researchers need not sit on their hands, waiting patiently until neuroscientists have worked out the details of low-level processing. This would be like saying that we cannot understand visual cortex until we have understood how the retina operates in detail (an argument actually advanced in the 1950s). There are many reasons to move ahead now, and study how the brain gives rise to cognition: (1) We will never understand *which* elementary processes contribute to cognition unless we study cognition; (2) we will never understand *how* processes interact during cognition unless we study cognition; and (3) we may never understand *all* of the functions of low-level processes unless we study their role in higher cognitive functions. Consider the study of building materials and architecture, for example. We must study the properties of bricks, boards, and so on if we want to understand the details of building construction; but if we don't study architecture, we will never understand why particular buildings are constructed the way they are. Moreover, by studying architecture, we are led to ask about specific properties of the material themselves—why, for instance, steel is necessary in some buildings and what properties of bricks make them useful for defining arches over doorways.

The chapters presented in this section illustrate these points well. Farah reviews evidence that mental imagery draws on processes used in like-modality perception. Farah shows that imagery can be understood in part by considering the roles of specific brain structures in perception and memory. Kosslyn and Thompson extend this general theme, providing a theory of such interactions (and maintaining that imagery actually plays a role in ordinary perception) and arguing that motor processes are invoked in mental imagery. Thus, we see in these two chapters examples of how our understanding of lower-level processes informs our understanding of higher cognitive functions, and also how the study of higher cognitive functions provides insights and hypotheses about the possible roles of lower-level processes. Dehaene takes this theme in a different direction, offering a particularly dramatic example of how low-level processes can contribute to high-level ones—i.e., mathematics. He discusses evidence that a “number line” representation exists in the intraparietal sulcus. Apparently, when exercising an abstract ability like arithmetic, we humans invoke spatial representations, much like those involved in some forms of mental imagery. Ivry and Fiez echo the general theme that low-level processes can best

be understood by their roles in high-level functions. They review evidence that the cerebellum, long characterized as the “slave of the cerebral cortex,” plays important roles in attention and cognition. They show that the functions of this complex structure can be understood only by considering its possible roles in different aspects of cognition.

The next three chapters shift the substantive focus to categories and concepts, but maintain the emphasis on explaining higher-level functions in terms of lower-level ones. Smith and Jonides review evidence for multiple ways of assigning an object to a category, each method being characterized by the lower-level mechanisms it recruits. As one example, Smith and Jonides provide neuroimaging evidence that rule-based categorization relies extensively on working memory, as witnessed by the activation of working-memory circuitry when subjects categorize novel objects by an explicit rule. The chapters by Martin, Ungerleider, and Haxby and by Caramazza deal with the conceptual knowledge involved in categorization. Using neuroimaging evidence from normal subjects, Martin, Ungerleider, and Haxby suggest that information about an object is represented in the brain as a distributed network of discrete cortical regions. Furthermore, within this cortical network, the features that define an object are stored close to the primary sensory and motor areas that were active when information about the object was acquired. (For example, information about the typical color of an object is stored close to color-perception areas.) Thus the organization of higher-level conceptual knowledge likely parallels the organization of low-level sensory systems—a remarkable example of the proposition that higher-level cortical function is based on lower-level principles. Caramazza's chapter also deals with the cortical representation of conceptual knowledge, although his focus is on studies of category-specific deficits observed in neurological patients (e.g., a selective deficit in knowledge about fruits and vegetables). He reviews the evidence that such deficits can be understood in terms of the distinction between perceptual and functional knowledge; but, finding this evidence wanting in several respects, he proposes alternative models of category-specific deficits. Importantly, some of these alternative models, like the perceptual/functional one, posit that conceptual knowledge can be understood in terms of lower-level features.

The final chapter in this section deals with the highest-level function covered here, namely, decision making. In particular, Tranel, Bechara, and Damasio focus on the interaction between decision making and affect. These authors review a specific hypothesis about this interaction, the somatic marker hypothesis, which proposes

that certain structures in prefrontal cortex use associations between aspects of the task and internal affective states to guide decision making. Much of the evidence for the hypothesis comes from studies of impaired decision making by neurological patients with selective dam-

age to key prefrontal areas. Because the affective states involved can be equated with signals from bioregulatory responses, the work again shows the utility of grounding the study of higher-level neural functioning in what is known about lower-level processes.

66 The Neural Bases of Mental Imagery

MARTHA J. FARAH

ABSTRACT The mind's eye was once shunned by psychologists as too subjective, too mentalistic a phenomenon for scientific study. In the 1970s imagery became an active research area, thanks to the concepts and methods of cognitive psychology, and we are now in the process of exploring its neural bases. This chapter reviews research with focally brain-damaged patients and with functional neuroimaging in normal subjects—research aimed at understanding the brain mechanisms underlying mental imagery. The view emerging from these studies is that many of the same modality-specific cortical areas activated by stimuli in visual perception are also activated by higher-order brain regions in imagery, including spatially mapped regions of occipital cortex. There is also evidence for a distinct image generation mechanism, required for the top-down generation of images from memory but not for bottom-up perception.

What color are the stars on the American flag? To answer this question, very likely you called up a mental image of the flag in your “mind’s eye,” and “saw” that the stars are white. The mind’s eye was once dismissed by psychologists as too subjective, too mentalistic a phenomenon for scientific study (cf. Skinner, 1978), but the development of the information-processing framework within cognitive psychology made mental imagery scientifically tractable. Early pioneers of imagery research devised many elegant and ingenious experimental paradigms to demonstrate the distinction between imagery and verbal thought, and to characterize imagery in objective information-processing terms (e.g., Kosslyn, 1980; Paivio, 1971; Shepard, 1978). Two schools of thought concerning imagery developed, giving rise to the so-called imagery debate.

The imagery debate

Starting in the late 1970s, two related issues concerning imagery emerged. (1) Does mental imagery involve some of the same representations normally used during visual perception, or does imagery involve only more abstract, post-perceptual representations? (For a more explicit discussion, cf. Finke, 1980; Shepard, 1978.) (2) Do mental images have a spatial, or array-like, format,

or are they propositional (symbolic or language-like) in format? Much of Kosslyn’s research was aimed at addressing this issue (cf. Kosslyn, 1980). The two issues are, in principle, independent, although given the fact that much of visual representation is array-like (e.g., Maunsell and Newsome, 1987), they are closely related.

Despite their straightforward, empirical nature, these issues proved difficult to settle using the experimental methods of cognitive psychology. Consider the classic image scanning experiments of Kosslyn (e.g., Kosslyn, Ball, and Reiser, 1978) for example. Kosslyn and associates instructed subjects to focus their attention on one part of an image, then move it continuously, as quickly as possible, to some other part of the image. They found that the time taken to scan between the two locations was directly proportional to their metric separation, just as if subjects were scanning across a perceived stimulus. This finding follows naturally from the view that images share representations with visual percepts, and that these representations have a spatial format. However, not all psychologists agreed with this interpretation. Various types of alternative explanations were proposed—explanations that accounted for the scanning findings (and many others) without hypothesizing shared representations for imagery and perception or a spatial format for imagery. These alternative explanations are discussed in detail by Farah (1988) as motivation for turning to neuropsychological evidence. Two examples are mentioned briefly here.

Pylyshyn (1981) suggested that subjects in imagery experiments take their task to be simulating the use of visual-spatial representations; hence, with their tacit knowledge of the functioning of their visual system, subjects are able to perform this simulation using nonvisual representations. Intons-Peterson (1983) suggested that subjects in imagery experiments may be responding to experimenters’ expectations; in fact, she has shown that at least certain aspects of the data in imagery experiments can be shaped by the experimenters’ preconceptions. Perhaps less plausible than the hypothesis that images are modality-specific visual representations and hence intrinsically spatial in format, these accounts have proved difficult to rule out. In fact, Anderson (1978) has argued that no behavioral data (i.e., sets of

MARTHA J. FARAH Department of Psychology, University of Pennsylvania, Philadelphia, Pa.

stimulus inputs paired with subjects' responses to those stimuli and the latencies of the responses) can ever distinguish alternative, nonvisual, theories of imagery from the visual-spatial theories.

One way out of this impasse is to turn to neuropsychological data, which are immune to many of the alternative explanations that plague the behavioral data (Farah, 1988). The methods of cognitive neuroscience, including lesion studies and functional neuroimaging studies, have the potential to be more decisive on the imagery debate because they provide more direct evidence on the internal processing stages intervening between stimulus and response in imagery experiments.

The brain bases of mental images: Modality-specificity and format

The studies relevant to the two issues of the imagery debate—are images visual, and do they have a spatial format?—include studies of brain-damaged subjects as well as measures of regional brain activity in normal subjects.

STUDIES OF BRAIN-DAMAGED PATIENTS If forming a mental image consists of activating cortical visual representations, then patients with selective impairments of visual perception should manifest corresponding impairments in mental imagery. This is often the case. For example, DeRenzi and Spinnler (1967) investigated various color-related abilities in a large group of unilaterally brain-damaged patients. They found an association between impairment on color vision tasks, such as the Ishihara test of color blindness, and on color imagery tasks, such as verbally reporting the colors of common objects from memory. Beauvois and Saillant (1985) studied the imagery abilities of a patient with a visual-verbal disconnection syndrome. The patient could perform purely visual color tasks (e.g., matching color samples) and purely verbal color tasks (e.g., answering questions such as “What color is associated with envy?”), but could not perform tasks in which a visual representation of color had to be associated with a verbal label (e.g., color naming). When the patient's color imagery was tested purely visually, she did well, easily selecting the color sample that represented the color of an object depicted in black-and-white. However, when the equivalent problems were posed verbally (e.g., “What color is a peach?”), she did poorly. In other words, mental images interacted with other visual and verbal task components as if they were visual representations. De Vreese (1991) reported two cases of color imagery impairment: One patient had left occipital damage and displayed the same type of visual-verbal disconnection as the patient just described, and the other had bilateral occipital dam-

age and displayed parallel color perception and color imagery impairments.

In another early study documenting the relations between imagery and perception, Bisiach and Luzzatti (1978) found that patients with hemispatial neglect for visual stimuli also neglected the contralesional sides of their mental images. Their two right-parietal-damaged patients were asked to imagine a well-known square in Milan, as shown in figure 66.1. When they were asked to describe the scene from vantage point A in the figure, they tended to name more landmarks on the east side of the square (each marked with a lowercase a in figure 66.1); that is, they named the landmarks on the right side of the imagined scene. When they were asked to imagine the square from the opposite vantage point, marked B on the map, they reported many of the landmarks previously omitted (because these were now on the right side of the image) and omitted some of those previously reported.

Levine, Warach, and Farah (1985) studied the roles of the “two cortical visual systems” (Ungerleider and Mishkin, 1982) in mental imagery, with a pair of patients. Case 1 had visual disorientation following bilateral parieto-occipital damage, and case 2 had visual agnosia following bilateral inferior temporal damage. We found that the preserved and impaired aspects of visual imagery paralleled the patients' visual abilities: Case 1 could neither localize visual stimuli in space nor accurately describe the locations of familiar objects or landmarks from memory. However, he was good at both perceiving object identity from appearance and describing object appearance from memory. Case 2 was impaired at perceiving object identity from appearance and describing object appearance from memory, but was good at localizing visual stimuli and at describing their locations from memory.

Farah and associates (1988) carried out more detailed testing on the second patient. We adapted a large set of experimental paradigms from the cognitive psychology literature—paradigms that had been used to argue either for the visual nature of imagery (the “picture-in-the-head” imagery) or for its more abstract spatial nature. Our contention was that both forms of mental imagery exist, contrary to much of the research in cognitive psychology aimed at deciding which of the two characterizations was correct. On the basis of the previous study, we conjectured that the patient with the damaged ventral temporo-occipital system would fail cognitive psychology's so-called visual imagery tasks but would have no problem with so-called spatial imagery tasks owing to his intact dorsal parieto-occipital system.

The visual imagery tasks included imagining animals and reporting whether they had long or short tails,

FIGURE 66.1 Map of the Piazza del Duomo in Milan. A and B are the two positions from which patients were asked to

imagine viewing the piazza; a and b are the respective landmarks the patients recalled from each imagined position.

imagining common objects and reporting their colors, and imagining triads of states within the U.S.A. and reporting which two are most similar in outline shape. The spatial imagery tasks included such mental image transformations as mental rotation, scanning and size scaling, and imagining triads of shapes and reporting which two are closest to one another. The patient was impaired relative to control subjects at the visual-pattern-color imagery tasks, but entirely normal at the spatial imagery tasks.

Although the foregoing studies implicate modality-specific visual representations in imagery, they are either ambiguous as to the level of visual representation involved, or they implicate relatively high-level representation in the temporal and parietal lobes. In a recent study, Farah, Soso, and Dasheiff (1992) examined the role of the occipital lobe in mental imagery. If mental imagery consists of activating relatively early representa-

tions in the visual system, at the level of the occipital lobe, then it should be impossible to form images in regions of the visual field that are blind owing to occipital lobe destruction. This predicts that patients with homonymous hemianopia should have a smaller maximum image size, or visual angle of the mind's eye. The maximum image size can be estimated using a method developed by Kosslyn (1978): Subjects are asked to imagine walking toward objects of different sizes and report the distance at which the image just fills their mind's eye's visual field and is about to "overflow." The trigonometric relation between the distance, object size, and visual angle can then be used to solve for the visual angle.

We were fortunate to encounter a very high-functioning, educated young woman who could perform the rather demanding task of introspecting on the distance of imagined objects at overflow. In addition, she could serve as her own control because she was about to

"I can get to within 15 feet of the horse in my imagination before it starts to overflow"

"The horse starts to overflow at an imagined distance of about 35 feet"

FIGURE 66.2 The effects of occipital lobectomy on the maximal mental image size of case MGS.

undergo unilateral occipital lobe resection for treatment of epilepsy. We found that the size of her biggest possible image was reduced after surgery, as represented in figure 66.2. Furthermore, by measuring maximal image size in the vertical and horizontal dimensions separately, we found that only the horizontal dimension of her imagery field was significantly reduced. These results provide strong evidence for the use of occipital visual representations during imagery.

The results from brain-damaged patients are generally consistent with the hypothesis that mental imagery involves representations within the visual system proper, including relatively early representations in the occipital lobe known to be spatial in format. But there are discrepant findings, as well. Goldenberg, Mulbacher, and Nowack (1995) described a case of cortical blindness following bilateral occipital lobe lesions; the patient performed well on some, but not all, imagery tasks, suggesting that occipital cortex may not be necessary for mental imagery. This patient did, however, retain some small islands of intact occipital cortex, and eventually recovered vision in the sectors of the visual field corresponding to the preserved cortex. Thus it is possible that this occipital cortex was also subserving her mental imagery.

More clear-cut cases of perceptual impairment with preserved imagery involve patients with agnosia. An apperceptive agnosic patient has been found to perform well on imagery tasks despite a perceptual impairment so severe that the patient could not reliably distinguish squares and circles (Servos and Goodale, 1995). Behrmann, Moscovitch, and Winocur (1994) and Bartolomeo

and colleagues (1998) describe associative agnosic patients who demonstrate good visual mental imagery abilities.

On the face of things, these observations conflict with the hypothesis that imagery and visual perception share representations. Of course, if we accept the alternative hypothesis—that imagery does not share representations with perception—the evidence of parallel impairments in imagery and perception is equally confounding. Is there some way to accommodate both the associations and the dissociations between imagery and perception?

One possibility is that there are general visual representations common to imagery and perception, in which case damage would generate associated impairments and disconnection from afferent perceptual inputs would generate the dissociations occasionally observed. In the light of this possibility, it is interesting that the MRI of the agnosic studied by Bartolomeo and associates (1998) shows predominantly white matter damage, undercutting intact visual association cortex (see their figure 1). A related possibility concerns damage to relatively early levels of cortical visual processing. Assume the damaged representations are among those shared by imagery and perception, not purely perceptual afferents, and consider the impact of interrupting processing at this stage: When the flow of processing is bottom-up or afferent, as in perception, the impact will be large because the majority of visual representations cannot be accessed. In contrast, when the flow of processing is top-down or efferent, as in imagery, the impact will be smaller because just a minority of the representations normally activated in imagery are unavailable. This possibility seems relevant in cases with evidence of early damage, such as apperceptive agnosia or the associative agnosia of Behrmann, Moscovitch, and Winocur (1994), whose perceptual impairment was evident on such low-level visual tasks as segmenting overlapping figures. A final possibility, which may interact with the previous one, concerns individual differences in imagery ability. Given that people differ in how fully they engage their early visual representations when generating mental images (see Farah and Peronnet, 1989), some people's mental imagery ability may be more susceptible to early visual system damage than others. The same hypothetical lesion in visual association cortex might interfere with one person's imagery, whereas an individual whose imagery was confined to higher levels of association cortex might be unaffected.

To conclude, in most (but not all) cases of selective visual impairments following damage to the cortical visual system, patients manifest qualitatively similar impairments in mental imagery and perception. Spatial attention impairments for the left side of the visual scene also

affect the left side of mental images. Central impairments of color perception tend to co-occur with impairments of color imagery. Higher-order impairments of visual spatial orientation sparing visual object recognition (and the converse) are associated with impairments of spatial imagery sparing imagery for object appearance (and the converse). Finally, hemianopia resulting from surgical removal of one occipital lobe is associated with a corresponding loss of half the mind's eye's visual field.

Two conclusions follow from these findings. First, at least some modality-specific cortical representations perform "double duty," supporting both imagery and perception. Second, those representations are functioning in analogous ways, specialized for the same kinds of visual or spatial information in both perception and imagery. Let us now turn to a different source of evidence on the relation between imagery and perception.

BRAIN IMAGING STUDIES IN NORMAL SUBJECTS
Starting in the mid-1980s, regional brain activity during mental imagery has been monitored in normal subjects using a variety of techniques. The earliest work in this vein was done with single photon emission computed tomography (SPECT). Roland and Friberg (1985) examined patterns of regional blood flow while subjects performed three different cognitive tasks, one of which was to visualize a walk through a familiar neighborhood, making alternate left and right turns. In this task (unlike the other tasks) blood flow indicated activation of the posterior regions of the brain, including visual cortices of the parietal and temporal lobes. These results are therefore consistent with the general hypothesis that mental imagery is a function of visual cortical areas. But they failed to support the more specific hypothesis of early, occipital involvement, due, at least partly, to incomplete monitoring of occipital cortex in this study.

Goldenberg and his colleagues (e.g., Goldenberg et al., 1987, 1989a,b, 1991, 1992) performed a series of blood flow studies of mental imagery using SPECT. Using very elegant experimental designs, they inferred which brain areas were activated by mental imagery. In these experiments, imagery tasks were closely matched with control tasks involving many of the same processing demands except for the mental imagery *per se*. Thus, for example, one imagery task was the memorization of word lists using an imagery mnemonic while its control task was memorization without imagery (Goldenberg et al., 1987). Another task involved answering questions of equal difficulty, which either did (e.g., "What is darker green, grass or a pine tree?") or did not (e.g., "Is the Categorical Imperative an ancient grammatical form?") require mental imagery (Goldenberg et

al., 1989a). In all of these studies, visual imagery was found to be associated with occipital and temporal activation. It is possible that the greater parietal involvement observed by Roland and colleagues (Roland and Friberg, 1985; Roland et al., 1987) is related to the need to represent spatial aspects of the environment in their mental walk task [cf. the findings of Farah and colleagues (1988) on dissociable visual and spatial mental imagery].

A study by Charlot and co-workers (1992) used SPECT while subjects generated and scanned images in the classic cognitive psychology image scanning paradigm developed by Kosslyn's group (1978). These authors also found activation of visual association cortex, including occipital cortex.

In general, the findings with SPECT are consistent with those of work with patients, showing visual cortical activity associated with mental imagery. Of greatest interest, perhaps, is the pronounced and consistent activation of occipital cortex observed in these studies. This suggests that imagery involves spatially mapped visual representations.

Event-related potentials (ERPs) have also been used to address the question of whether visual mental imagery has a visual locus in the brain. In one study, Farah and colleagues (1988) used ERPs to map out, in space and in time, the interaction between mental imagery and concurrent visual perception. We found that imagery affected the ERP to a visual stimulus early in stimulus processing—within the first 200 ms. This implies that imagery involves visual cortical regions that are normally activated in early visual perception. The visual ERP component that is synchronized with the effect of imagery, the N1, is believed to originate in areas 18 and 19, implying a relatively early extrastriate locus for imagery in the visual system. Interpolated maps of the scalp-recorded ERPs were also consistent with this conclusion.

A second series of studies (Farah et al., 1989) took a very different approach to localizing imagery in the brain using ERP methods. Rather than observing the interaction between imagery and concurrent perception, we simply asked subjects to generate a mental image from memory, in response to a visually presented word. By subtracting the ERP to the same words when no imagery instructions were given from the ERP when subjects were imaging, we obtained a relatively pure measure of the brain electrical activity that is synchronized with the generation of a mental image. Again, we constructed maps of the scalp distribution of the ERP imagery effect in order to determine whether the maxima lay over modality-specific visual perceptual areas. Despite the very different experimental paradigm, we

found a highly similar scalp distribution to the previous experiment, clearly implicating visual areas. When the experiment was repeated using auditory word presentation, the same visual scalp topography was obtained. Control experiments showed that the imagery effects in these experiments were not due to the cognitive effort expended by subjects when imaging (as opposed to imagery *per se*), or to eye movements.

Farah and Peronnet (1989) reported two studies in which subjects who rated their imagery as relatively vivid showed a larger occipital ERP imagery effect when generating images than subjects who claimed to be relatively poor imagers. This result, which we then replicated under slightly different conditions, suggests that some people are more able to efferently activate their visual systems than others, and that such people experience especially vivid imagery.

A different study (Uhl et al., 1990) used scalp-recorded DC shifts to localize brain activity during imagery for colors, faces, and maps. Following transient positive deflections of the kind observed by Farah's group (1989), a sustained negative shift was observed over occipital, parietal, and temporal regions of the scalp. Consistent with the different roles of the two cortical visual systems, the effect was maximal over parietal regions during map imagery, and maximal over occipital and temporal regions during face and color imagery.

With the advent of PET, the spatial localization of cognitive neuroimaging improved greatly, and researchers soon applied this technique to experiments on imagery. In an early study, Roland and co-workers (1987) repeated their mental walk task with PET, again finding only higher-order visual association cortices activated. In subsequent years, Roland and colleagues conducted a number of simple experiments intended to map the neural substrates of imagery, without observing reliable occipital activation (Roland and Gulyas, 1994).

Kosslyn and colleagues (1993) also used PET to localize imagery, obtaining results more consistent with the data from focally lesioned patients (cf. Farah et al., 1992) and the preponderance of neuroimaging studies so far reviewed. In the first two of their experiments, subjects viewed grids in which block letters were either present or to be imagined, and judged whether an X occupying one cell of the grid fell on or off the letter. Comparisons between imagery and relevant baseline conditions showed activation of many brain areas, including occipital visual cortex. In a third experiment, subjects generated either large or small images of letters of the alphabet with eyes closed; then the researchers directly compared the two imagery conditions. They found that the large images activated relatively more anterior parts of visual cortex than the small ones, con-

sistent with the known mapping of the visual field onto primary visual cortex. A later study (Kosslyn et al., 1995) also found that occipital patterns of activation varied according to image size in a way that is consistent with the anatomy of primary visual cortex. Other PET studies of imagery have agreed with these studies insofar as occipital cortex was activated, but have disagreed as to whether primary visual cortex is involved (e.g., Mellet et al., 1995, 1996).

Recently, functional magnetic resonance imaging (fMRI) has allowed researchers to obtain blood flow-based images of function with good temporal as well as spatial resolution. The earliest study to exploit these qualities for the study of mental imagery (Le Bihan et al., 1993) measured brain activity in primary visual cortex as subjects alternately viewed flashing patterns and imagined them. The results for one subject, as shown in figure 66.3, provide a striking demonstration of the involvement of primary visual cortex in mental imagery as well as in perception.

D'Esposito and colleagues (1997) measured regional activity throughout the brain with fMRI while subjects performed the image generation task of Farah and co-workers (1989): either passively listening to words or generating mental images of the words' referents. We found temporo-occipital activation, extending further into occipital cortex for some subjects than for others, but in no case reaching primary visual cortex.

Perhaps not surprisingly, there are differences in the conclusions that can be drawn from the studies reviewed here, which varied in their imaging techniques and cognitive tasks. Nevertheless, some generalizations can be made. In almost every study, mental imagery activates modality-specific visual cortical areas, including spatially mapped regions of occipital association cortex.

THE IMAGERY DEBATE REVISITED In Anderson's (1978) discussion of the intrinsic ambiguities of behavioral data for resolving the imagery debate, he suggested that physiological data might someday provide a decisive answer. Just two decades later, that day may have arrived. There is much more to find out and some current conclusions doubtless need revision; nevertheless, we can point to a body of converging evidence that supports the modality-specific visual nature of mental images, suggesting that at least some of their neural substrates have a spatial representational format. That is, damage to visual areas representing such specialized stimulus properties as color, location, and form results in the loss of these properties in mental imagery. Spatially delimited impairments of visual attention and of visual representation are accompanied by corresponding impairments in imagery. Psychophysiological studies using blood flow imaging methods and ERPs

FIGURE 66.3 Plot of activity over time in primary visual cortex measured by MRI, as a function of the subject's activity. Upper panel: The subject was resting between two real visual

stimuli. Lower panel: The subject imagined the stimuli between actual stimulus presentations.

have operationalized imagery in a wide variety of ways; these include instructions to take a mental walk, imagery mnemonics, general knowledge questions about the appearances of familiar objects, the effect of imagery on concurrent perception, instructions to image common objects,

self-reported individual differences in vividness of imagery, and judgments about imagined letters of the alphabet. Across all of these superficially different tasks, indices of regional brain activity implicate modality-specific visual cortex in mental imagery.

During visual perception, the stimulus initiates a cascade of processing. Beginning at the retina, this processing passes through various intermediate representations in the LGN and occipital cortex that roughly preserve the spatial mapping of the retina, then culminates with relatively abstract representations of object appearance and location in temporal and parietal cortices. The evidence just reviewed suggests that, during imagery, the direction of information flow is reversed, and some of the intermediate, spatially mapped, representations are reactivated by higher-level mechanisms rather than by a stimulus. The process of activating visual representations top-down rather than bottom-up is known as image generation.

An important difference between perception and imagery concerns the automaticity of the processes involved. One cannot see a familiar object and fail to recognize it. But one can think about familiar objects without inexorably calling to mind a visual mental image. This suggests that the activation of spatially mapped visual cortical regions from memory requires the intervention of a separate, attention-demanding process, needed for image generation but not for visual perception and object recognition.

Farah (1984) reviewed the neurological literature on imagery impairments and identified a set of cases in which perception was grossly intact. In subsequent years, a small number of additional cases of selectively impaired imagery have been reported (e.g., Farah, Levine, and Calvanio, 1988; Goldenberg, 1992; Grossi, Orsini, and Modafferi, 1986; Riddoch, 1990), as well as similar but weaker dissociations in subgroups of patients in group studies (Bowers et al., 1991; Goldenberg, 1989; Goldenberg and Artner, 1991; Stangalino, Semenza, and Mondini, 1995). On the face of things, the preservation of perceptual abilities in the context of impaired imagery is consistent with the existence of a distinct image generation process.

Goldenberg and Artner (1991) propose an alternative possibility—that image generation requires higher-quality visual representations than normal perception—and show that patients with an apparent image generation deficit perform poorly on subtle visual discriminations (e.g., between a bear with pointy ears and a bear with rounded ears). At a very general level, one can view these alternatives as mutually compatible. Image generation may be just the additional visual processing that is needed for difficult perceptual tasks when, for example, one forms a search image or, in the case of the study at hand, visualizes a bear from memory to check its ears.

The localization of mental image generation has been a controversial topic. Although mental imagery was for many years assumed to be a function of the right hemisphere, Ehrlichman and Barrett (1983) pointed out that there was no direct evidence for this assumption. Farah (1984) noted a trend in the cases she reviewed for left posterior damage. Later, she suggested that the left temporo-occipital area may be critical (Farah et al., 1988). The recent focally damaged cases mentioned above (Farah et al., 1988; Goldenberg, 1992; Grossi, Orsini, and Modafferi, 1986; Riddoch, 1990) have supported this suggestion, as have the group studies to varying degrees (most clearly Goldenberg and Artner, 1991; Stangalino, Semenza, and Mondini, 1995). The rarity of cases of image generation deficit suggests that this function may not be strongly lateralized in most people; however, when impairments are observed after focal unilateral damage, the left or dominant hemisphere is implicated.

This conclusion is supported by the majority of neuroimaging studies, although exceptions exist. Interested readers may consult my review article (Farah, 1995) on image generation for the neuroimaging evidence as of the mid-1990s concerning the role of left temporo-occipital cortex in image generation (see also D'Esposito et al., 1997).

Conclusions

What neural events underlie the generation of a visual mental image? Over the past fifteen years a variety of cognitive neuroscience methods have been brought to bear on this question, and a reasonably consistent answer seems to be emerging. Mental imagery is believed to be the efferent, or top-down, activation of some subset of the brain's visual areas. In other words, at least some of our cortical visual areas are used both for imagery and perception. Furthermore, these areas subserve the same types of representational functions in both cases, carrying information specifically about color, shape, spatial location, and so on.

Some of the visual areas implicated in imagery, by both lesion and imaging studies, are known to be spatially mapped. This finding provides evidence for the spatial nature of image representation, in contrast to the view that imagery is a propositional, or language-like, mode of representation. Finally, the existence of a distinct mechanism for image generation, one separate from the processes needed for normal bottom-up perception, is supported by dissociations between imagery and perception in brain-damaged patients. The evidence from patients strongly implicates a left temporo-occipital localization for this process; neuroimaging data are mixed, but generally support this conclusion.

67 Shared Mechanisms in Visual Imagery and Visual Perception: Insights from Cognitive Neuroscience

STEPHEN M. KOSSLYN AND WILLIAM L. THOMPSON

ABSTRACT A confluence of behavioral, lesion-deficit, and neuroimaging data has shown that visual mental imagery and visual perception rely on some common brain mechanisms. However, other data show that the two do not recruit identical systems. In this chapter we characterize the information-processing roles of the mechanisms shared by visual imagery and perception. Then we use the theory to examine apparent disparities and inconsistencies in the neuroimaging literature and to consider different ways in which visual mental images can arise.

Mental imagery has long been thought to share mechanisms with like-modality perception. If so, we can take advantage of the rich literature on perception when theorizing about mental imagery. In fact, three classes of findings indicate that the two functions draw on some of the same mechanisms (for reviews, see Craver-Lemley and Reeves, 1987, 1992; Farah, 1988; Finke, 1989; Kosslyn, 1994; Shepard and Cooper, 1982). One class of findings has focused on behavioral phenomena. For example, following long tradition (e.g., Perky, 1910; Segal and Fusella, 1970), Craver-Lemley and Reeves (1987) demonstrated that visual perceptual acuity may be diminished when subjects visualize a pattern that overlaps with a perceptual stimulus. In addition, Finke, Johnson, and Shyi (1988), Intraub and Hoffman (1992), and Johnson and Raye (1981) showed that subjects may not be able to distinguish clearly between actually perceiving a stimulus versus simply “seeing” it in imagination. Moreover, Demarais and Cohen (in press) showed that people make more horizontal than vertical eye movements when “inspecting” a horizontal array in an image, but more vertical than horizontal eye movements when inspecting a vertical array in an image. A second class of findings includes many reports that brain damage causes parallel impairments in imagery and perception. For instance, patients whose unilateral visual neglect causes them to ignore half of perceptual space also ignore that

same half of “representational space” during imagery (Bisiach and Luzzatti, 1978); and the inability of some brain-damaged patients to recognize faces is accompanied by a similar inability to visualize faces (Shuttleworth, Syring, and Allen, 1982). Yet a third class of findings focuses on similarities in the brain areas that are activated during imagery and perception. Goldenberg and colleagues (1989), for example, used single photon emission computed tomography (SPECT) to examine differences in brain events when subjects evaluated the veracity of sentences with and without imagery, and reported an increase in blood flow in posterior visual areas of the brain during imagery. Similar effects during visual imagery were found by Farah and colleagues (1988), who recorded evoked potentials over the posterior scalp. Roland and associates (1987) also report activation in visual areas during visual imagery tasks [although not in the posterior regions found by Goldenberg et al. (1989), Kosslyn et al. (1993), and others; for reviews, see Roland and Gulyas (1994) and accompanying commentaries, as well as Kosslyn et al. (1995b) and Thompson and Kosslyn (in press)].

Other findings, however, paint a more complex picture. For example, two groups (Behrmann, Winocur, and Moscovitch, 1992; Jankowiak et al., 1992) report cases of brain-damaged patients whose imagery is intact in spite of impaired perceptual abilities, and Farah (1984) reviews reports of patients who had impaired imagery abilities in the face of intact perceptual abilities. These observations clearly show that only some of the same processes are recruited during both imagery and perception. Such findings are unsurprising, given that imagery relies on previously organized and stored information whereas perception requires on-the-spot computations, including figure-ground segregation, recognition, and identification. Thus, imagery relies on top-down mechanisms that may not be necessary in all perception, and perception relies on bottom-up mechanisms that may not be used in many imagery tasks.

STEPHEN M. KOSSLYN and WILLIAM L. THOMPSON Department of Psychology, Harvard University, Cambridge, Mass.

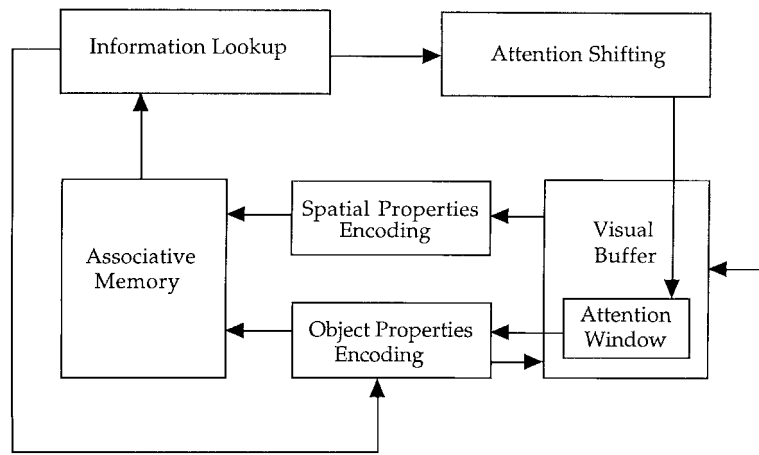

FIGURE 67.1 Six subsystems shared by visual imagery and perception.

Nevertheless, visual imagery and perception appear to share a core set of processes. Here, we begin by describing a positron emission tomography (PET) study that examined brain areas shared by visual mental imagery and high-level visual perception. The theory developed by Kosslyn (1994) is then drawn upon to characterize the roles of the shared processes. Following this, we use this theory to help us offer possible explanations for divergent results in the neuroimaging literature. Finally, we consider how the system may give rise to alternative types of imagery that may be used in different types of tasks.

Imagery and perception: Shared brain areas

Kosslyn, Thompson, and Alpert (1997) investigated the commonalities and differences in brain activation during visual imagery and visual perception. In order to show the strength of our analysis, we examined two tasks that appear, on the surface, to be very different. The perceptual task required the participants to judge whether the words named line drawings of objects. In the baseline condition, the objects were shown from typical, or canonical, viewpoints, in which case recognition and identification should be accomplished in a straightforward manner. In the comparison condition, the objects were shown from atypical, or noncanonical, viewpoints. In this case, objects would not be recognized immediately, but only after more detailed processing had occurred. We predicted that in this condition the first encoding would be used to generate a hypothesis as to the identity of the object. This hypothesis would then be tested using mechanisms of top-down search. In order to decide whether the word did, in fact, name the pictured object, stored information representing specific properties of the candidate object would be accessed, then attention

would be directed to the place where a distinctive property should be found and additional information would be encoded. If the sought property is located, it would support the hypothesis, allowing a decision to be made (for additional details, see Kosslyn, 1994).

More specifically, the theory predicts that when one identifies an object from a noncanonical, rather than a canonical, viewpoint, the brain areas that implement certain subsystems would become more strongly activated. All of these subsystems would be used during an additional encoding cycle, when one seeks a distinctive property of the hypothesized object. Kosslyn and co-workers (1994) in fact found more activation in a network of brain regions when subjects judged the identities of objects portrayed from noncanonical viewpoints (the anatomical predictions were based on prior research findings, principally using nonhuman primates; for reviews, see Felleman and Van Essen, 1991; Kosslyn, 1994; Maunsell and Newsome, 1987; Ungerleider and Mishkin, 1982; Van Essen and Maunsell, 1983; Van Essen, 1985). Our interpretation of the findings rests on the following characterization of the subsystems used to recognize and identify objects (see figure 67.1).

VISUAL BUFFER If supplementary information must be registered in order to identify an object perceived from a noncanonical point of view, we predict activation in a subsystem we call the “visual buffer.” This structure plays a key role in figure-ground segregation and should be recruited more often if additional parts or properties must be encoded. The visual buffer is composed of a set of topographically organized brain areas, with “earlier” areas (e.g., Areas 17 and 18) providing the highest spatial resolution. Neurons in Areas 17 and 18 are characterized by smaller receptive fields than those in “later” areas (e.g., Area V4), so earlier areas can rep-

resent spatial variations that cannot be resolved by later areas. Earlier areas must therefore be drawn upon to represent high-resolution visual stimuli.

OBJECT-PROPERTIES ENCODING Activation was also observed in areas responsible for encoding object properties (e.g., shape or color) and matching them to stored visual memories. The object-properties-encoding subsystem we posit relies on the middle and inferior temporal gyri of humans (e.g., see Bly and Kosslyn, 1997; Gross et al., 1984; Kosslyn et al., 1994; Levine, 1982; Tanaka et al., 1991; Sergent, Ohta, and MacDonald, 1992; Sergent et al., 1992; Haxby et al., 1991; Ungerleider and Haxby, 1994; Ungerleider and Mishkin, 1982). *Recognition* occurs when a visual input matches a stored visual memory in this structure; when an object is recognized, one knows that it has been seen before.

SPATIAL-PROPERTIES ENCODING Spatial properties (e.g., location and size) are encoded at the same time as object properties. This subsystem relies on the posterior parietal lobes; thus, if additional parts and their spatial relations must be encoded in the noncanonical condition, we also expected additional activation in this region (e.g., Andersen, 1987; Andersen, Essick, and Siegel, 1985; Corbetta et al., 1993; Ungerleider and Haxby, 1994; Ungerleider and Mishkin, 1982). Such activation was in fact observed.

ASSOCIATIVE MEMORY Information carried by the pathways that register spatial and object properties must converge somewhere in the brain; both object and spatial properties furnish information useful for object identification (in addition, people can remember the particular locations of objects, which itself suggests that the two streams are conjoined at some point in processing). In fact, Felleman and Van Essen (1991) review findings that suggest several sites of convergence of the two pathways. We thus propose an “associative memory” subsystem that combines information from the two types of properties and compares this information to stored multimodal and amodal representations. We hypothesize that this structure is implemented by cortex in Area 19 and the angular gyrus (for evidence, see Kosslyn, Thompson, and Alpert, 1995). When input matches a stored representation here, the stimulus has been *identified*. When an object is identified, one has access to information associated with it, such as its name and categories to which it belongs. Thus, recognition arises when modality-specific representations are activated, whereas identification arises when multimodal and amodal representations are activated. (Consider, for example, what happens when you see someone and know

that you know her, but you can recall neither her name nor the context in which you met. This is an example of recognition without identification.) If the identity and location of distinctive parts are looked up, then encoded in the noncanonical but not the canonical condition, we should find more activation in the neural structures that implement this system. And in fact, such observation was observed.

INFORMATION LOOKUP If the input does not exactly match a stored representation in the object-properties-encoding subsystem, then the closest match may be treated as a hypothesis. When this occurs, additional information about the candidate object is gathered. We propose that an “information lookup” subsystem actively seeks supplementary information from stored memories, which permits the search for distinct properties. This subsystem, like all the others, is always operating, but operates more or less vigorously in different situations. If a stimulus is recognized confidently, the output from the object-properties-encoding subsystem will strongly activate a single representation in associative memory, so the information lookup subsystem does not run to completion. But if a poor match is found, no single stored representation is fully activated. In this case, the representation in associative memory that is most strongly activated following the tentative recognition will be accessed, and associated information (such as a particular mark or prominent part of an object) will be sought in top-down search. This subsystem relies on tissue in the dorsolateral prefrontal cortex, and plays a role in “working memory” (for supporting evidence, see Kosslyn, Thompson, and Alpert, 1995; cf. Goldman-Rakic, 1987).

ATTENTION SHIFTING Finally, we posit an “attention shifting” subsystem that changes the focus of one’s attention to the possible location of a distinctive property or characteristic, allowing such a characteristic to be encoded. This subsystem relies on a network that includes the frontal eye fields, superior colliculus, and superior posterior parietal lobes, in addition to other regions (see Corbetta et al., 1993; LaBerge and Buchsbaum, 1990; Mesulam, 1981; Posner and Petersen, 1990). In addition to shifting the locus of attention, this subsystem primes the representation of the sought part or property in the object-properties-encoding subsystem. Such priming allows the system to encode the sought part or property more easily (for evidence of such priming in perception, see Kosslyn, 1994, pp. 287–289; McDermott and Roediger, 1994). If more parts or properties are encoded in the noncanonical than the canonical condition, then the neural structures that implement these processes should

be more strongly activated in the noncanonical condition. We found activation in many of the structures used in attention.

We have summarized the functions of each subsystem as they are used in visual object identification, but each subsystem could also play a role in visual mental imagery. For example, consider the imagery task used by Kosslyn and colleagues (1993; experiment 2). Superficially, the task seems completely different from the object identification task; no objects are shown and name verification is not required. Instead, in the baseline condition the subjects see a lowercase letter followed by a 4×5 grid that contains an X probe in one cell. The subjects are merely told to respond when they have seen the grid. During the imagery condition, the same stimuli appear, but now the subjects are told that the lowercase letter is a cue to visualize the corresponding (previously learned) uppercase letter within the grid. Subjects must then decide whether the X would fall on a portion of the uppercase letter if the letter were in fact in the grid, or whether the X would fall in a cell not occupied by the letter. This task was designed by Podgorny and Shepard (1978) and employed by Kosslyn and co-workers (1988, 1993) to study the process of generating an image in short-term memory on the basis of information stored in long-term memory.

Given the evidence that imagery shares mechanisms with like-modality perception, it is reasonable to ask how the six functions schematized in figure 67.1 could come into play when a visual mental image is generated. The process of generating an image of an uppercase letter would begin when the information lookup subsystem retrieves a description of the letter's shape (which includes details about its parts and their locations) from associative memory. The attention-shifting subsystem shifts attentional focus to the location where the first segment should be placed, in the same way that one would attend to the possible location of a distinctive part during top-down hypothesis testing in perception. In imagery, however, the image must be generated at the location. According to our theory, forming a visual mental image relies on the mechanism that primes the representation (in the object-properties-encoding subsystem) of an expected object or part during perception. However, in imagery this priming is so strong that the shape itself is reconstructed in the visual buffer (see Kosslyn, 1994, for a review of the possible underlying anatomy, physiology, and computational mechanisms). That is, the anticipation of perceiving the object is so strong that an image of the object is imposed on the visual buffer. At least in the monkey, visual long-term memories are not stored in a topographically organized form, but rather are coded in columns that specify relatively abstract

properties (e.g., see Fujita et al., 1992). Thus, reconstructing the geometric layout of a shape requires "unpacking" the stored information and reconstructing the shape in lower-level, topographically organized areas. Imagery serves to make explicit the implicit spatial properties of an object.

Once the visual buffer contains the image of the first segment, the process is repeated for the second segment. In this case, the description of the letter is again accessed, attention is shifted appropriately, and another part is added. This view, then, predicts that parts are added to an image sequentially. And, in fact, in the grid-and-X task (Kosslyn et al., 1988), people judged X marks fastest if they fell on the first segment that is typically drawn, next fastest on the second segment, and so forth. This ordering of times was not observed when the image was formed before the X mark was presented, or when the subjects actually saw a dim uppercase letter in the grid. The ordering of times is as expected if segments are generated one segment at a time, and more segments had to be generated before "later" segments were included in the image.

According to this theory, once an image is generated (i.e., a pattern of activation is imposed in the visual buffer), further processing occurs in the same way that it occurs during perception: The object and spatial properties are encoded, then patterns and properties can be identified and spatial relations computed. Thus, for example, one can visualize the uppercase version of the first letter of the alphabet and "see" that there is a triangular shape enclosed in it, even though one had never explicitly considered this before. Similarly, one can visualize the word TREE in lowercase letters, and "see" that the last letter is not as high as the first.

We analyzed the PET data from the grids imagery task and picture verification task together, and we observed which areas were activated in both experimental conditions more than in both baseline conditions; by combining the conditions in this way, we could determine where activation generalized over both sets of conditions. As figure 67.2 shows, the areas activated in common by the perception and imagery tasks are easily organized according to the scheme outlined in figure 67.1. First, we discovered activation in left Area 18, a topographically organized region that implements part of the visual buffer. Second, we discovered common sites of activation in regions that implement the object-properties-encoding subsystem, in particular a left occipitotemporal area that included portions of the middle temporal gyrus and the right lingual gyrus. Third, we discovered common sites of activation in regions that implement the spatial-properties-encoding subsystem, namely, bilateral activation in the inferior parietal lobes.

(IMAGERY + NONCANONICAL) - (IMAGEBASE + CANONICAL)

FIGURE 67.2 Areas activated in common by visual imagery and visual perception. The panels on the left illustrate the left hemisphere, and those on the right, the right hemisphere. The top panels illustrate the lateral surface, and the bottom, the medial

surface. Triangles indicate the location of the most activated voxel in an area, with a Z value greater than 3.1. (From Kosslyn, Thompson, and Alpert, 1997.)

Fourth, we found common activation in regions that we hypothesize to implement associative memory. In the left hemisphere, two distinct points were detected, one in the angular gyrus and the other in Area 19; in the right hemisphere, two areas of activation in Area 19 (one merging into the angular gyrus) emerged. Some of these regions are very near to areas reported by Kosslyn, Thompson, and Alpert (1995), who provided evidence that such activation reflects the operation of associative memory. Fifth, we discovered activation in areas that have been taken to implement the information lookup subsystem, specifically in the dorsolateral prefrontal cortex. The lateralization to the left would be predicted if this region has a particular specialization for seeking information about “categorical” spatial relations (cf. Kosslyn et al., 1995a, 1998). Sixth, activation was also observed in areas that implement attention-shifting processes, namely the bilateral precuneus and the right superior parietal lobe (cf. Corbetta et al., 1993).

In short, the results are easily interpreted within the context of the theory. Nevertheless, some unpredicted points of activation were also discovered. In particular, there was common activation in the left precentral gyrus, an area that Decety and colleagues (1994) have taken to be involved in motor-related imagery. Thus it is possible that motor processes may be involved in both types of tasks described here. However, a more straightforward interpretation is that this finding reflects activation in the frontal eye fields. Paus (1996) reviews the blood flow and lesion study literature and deduces that the most likely locus of human frontal eye fields is the most caudal part of superior frontal sulcus, very near the precentral sulcus. However, this inference diverges with the long-held view that Brodmann’s Area 8 contains the human frontal eye fields; thus, the issue is best left open at present.

Finally, given the double dissociation between imagery and perception, we also asked which areas were more activated in one task than the other. Two areas in the right hemisphere, the middle temporal gyrus and the orbitofrontal cortex, were more activated in perception than imagery. In contrast, five areas were more activated in imagery than perception—two in the left inferior parietal lobe, the right superior parietal lobe, Area 19, and an area that included parts of Area 19 and the angular gyrus. Thus, a total of 21 areas were activated, with two-thirds of them activated in common by imagery and perception. If more areas are activated solely by imagery than perception than vice versa, we would expect to find more cases of brain-damaged patients who have disrupted imagery without disrupted perception than vice versa, which appears to be the case.

Resolving disparate results

A major issue currently debated within the neuroimaging literature is whether early visual cortex is activated during imagery. The theory that we have outlined leads us to expect images to rely on topographically organized areas in the occipital lobe, the site of the visual buffer. Some studies have even found activation in the first cortical visual area (known as Area V1, Area 17, primary visual cortex, striate cortex, and Area OC) when subjects close their eyes and visualize objects (e.g., Chen et al., 1996, 1998; Damasio et al., 1993; Kosslyn et al., 1993; Kosslyn et al., 1995b, 1996, 1999; LeBihan et al., 1993; Menon et al., 1993; Putz et al., 1996; Sabbah et al., 1995). Other studies have not found such activation (e.g., Charlot et al., 1992; Fletcher et al., 1995; Roland and Gulyas, 1994; Roland et al., 1987; Mellet et al., 1993, 1995, 1996). Because it is often difficult to be certain whether activation is in Area 17 or 18, and both areas implement high-resolution components of the visual buffer, we find it convenient to group them together under the rubric of medial occipital cortex (MOC).

Studies in which activation in the earliest visual areas is observed often require subjects to generate high-resolution images (but also vary in other ways, for instance, by having resting baseline conditions; see Kosslyn et al., 1995b). Sharper, more vivid images would result when neurons in earlier visual areas are recruited; these areas preserve finer spatial variations than do those in later areas. Thus, one possible explanation for the divergent findings is that MOC is engaged only when one must represent objects in high-resolution images. This account makes sense if it requires more effort to generate high-resolution images than to generate low-resolution images; thus, one would not form a high-resolution image unless performance of the task demands it.

If this account is true, we would predict that patterns requiring higher resolution would be more difficult to visualize than similar patterns requiring a lower degree of resolution. Kosslyn, Sukel, and Bly (1999) tested this hypothesis by asking subjects either to view or visualize displays that featured four quadrants, with each quadrant containing a pattern made up of a set of stripes. In two experiments, one of the displays featured only relatively narrow stripes, whereas another display featured only relatively thick stripes. High resolution is required to resolve narrow stripes, whereas only low resolution is necessary to resolve thick stripes. The task required the subjects to compare sets of stripes in different quadrants, then decide which set was longer, had more separation between the stripes, was tilted more, or was wider. When the participants visualized the displays, they required more time to compare high-resolution patterns

than low-resolution patterns; however, when the subjects actually perceived the displays, both high- and low-resolution, they compared the patterns equally easily. This result is in line with the notion that greater effort is required to generate high-resolution images. Furthermore, the third experiment in the series furnished strong support for the inference that imagery was indeed used in this task. In this experiment, the stimuli in one condition were four oblique sets of stripes (one per quadrant) and those in another condition were four vertical or horizontal sets of stripes (one per quadrant). During both perception and imagery, subjects made more errors when they compared oblique stimuli; and in imagery, they also required more time for the oblique stimuli. The stimuli were in fact identical except for orientation (and the orientation judgment was replaced, and thus orientation per se did not figure in the comparisons). This "oblique effect" has been well documented in perception (Appelle, 1972), but few outside the field of vision research are aware of it. Thus, it is highly unlikely that subjects were merely responding to experimenter demands or tacit knowledge in producing this effect; rather, this finding is good evidence that imagery and perception draw on common mechanisms.

Thompson and Kosslyn (in press) reviewed all available neuroimaging studies of imagery with a view to discovering the conditions in which different neural structures are invoked during imagery. The review revealed that, of the 42 studies where Areas 17 and 18 were examined, 25 reported activation in at least one of those areas. Based on these findings, Thompson and Kosslyn performed a meta-analysis in which each study was coded for various characteristics, which served as independent variables in the analysis. The dependent variable was a binary code expressing the presence or absence of MOC activation. These values were regressed onto the independent variables. This analysis revealed that the strongest predictor of MOC activation was the requirement to use high-resolution imagery.

Further consideration of the theory outlined in figure 67.1 suggests another possible, but not exclusive, account for the disparate reports of MOC activation. We note that in the monkey, the efferent connections from the inferior temporal lobe to the medial occipital lobe are diffuse; they are not point-for-point backward projections that mirror the afferent connections (e.g., Douglas and Rockland, 1992). To form an image, however, the feedback from higher-level areas need not necessarily define a precise image, mapping point-for-point from stored memories to the visual buffer. Rather, this feedback could serve to define an "attractor" in the visual buffer, which in turn causes activity to be organized in particular ways (cf. Hinton and Shallice, 1991).

If so, the system should operate more effectively if there is random "noise" in the areas that implement the visual buffer, noise that can be amplified and organized in accordance with feedback. The analogous case is listening to white noise and hearing voices or melodies within it; the same kinds of mechanisms presumably amplify and organize selected aspects of the noise. This idea led us to notice a previously overlooked aspect of the neuroimaging literature on visual imagery: In many studies in which subjects were reported to be blindfolded or tested in pitch-dark conditions, there was a failure to find activation of MOC during imagery. It is possible that even a small amount of diffuse light coming in from closed eyelids is sufficient to provide enough activation for top-down processes to amplify and augment it. Future studies will need to be designed to test this hypothesis directly.

Types of imagery

The system outlined in figure 67.1 could operate in more than one way, and there is reason to believe that the subsystems function differently in different tasks. For example, when Mellet and colleagues (1995) contrasted perception and imagery, their study yielded results very dissimilar to ours. Their experiment required subjects to use mental imagery to scan a map of an island or actually to look at and scan the map. When imagery and perception were directly compared, more activation was present in perception bilaterally in primary visual cortex, the superior occipital gyrus, the inferior occipital gyrus, the cuneus, the fusiform/lingual gyri, and superior parietal cortex. Many of these areas may be particularly involved in visual search. Conversely, more activation was found in imagery than perception bilaterally in the superior temporal and precentral gyri, as well as in the left dorsolateral prefrontal cortex (DLPFC), inferior frontal cortex, and in the supplementary motor area, anterior cingulate, median cingulate, and cerebellar vermis. In addition, Mellet and co-workers were not able to detect any activation in Areas 17 or 18 during the imagery task. These results suggest that the imagery task was performed using spatial representations (possibly in conjunction with motor processes), which rely on only part of the system outlined in figure 67.1.

In more recent work, Mellet and colleagues (1996) used a different type of spatial task, and again found no evidence of MOC activation in imagery. In this case, the subjects' task was to listen to a series of spatial directions, which were to be used to generate a mental image of a multi-armed object. The parts of the object were distinguished only by their direction and relative length, both of which are spatial properties. Roland and colleagues

(1987; see also Roland and Friberg, 1985), also using spatial directions, did not detect any MOC activation when they asked subjects to imagine walking along a path, making left or right turns at each junction. Again, areas that implement spatial and attentional processing were activated in these studies.

To make sense of these various findings, it is useful to consider three different types of imagery. First, there is the type of imagery used by Mellet and colleagues (1996) and Roland and colleagues (1987). Such imagery appears to be based on the mental representation of spatial relations, rather than that of shapes, textures, or colors. Within the scheme outlined in figure 67.1, this type of processing would invoke neither the visual buffer nor the object-properties-encoding subsystem; but it would activate the rest of the system, which is implemented in the posterior parietal lobes, DLPFC, and the angular gyrus/Area 19 as well as various areas that allocate attention. In addition, processing of this kind may often make use of motor processes (e.g., see Berthoz, 1996; Jeanerod et al., 1995). It is not clear to us that visual imagery is actually used in these sorts of situations. If there is a visual image (i.e., a pattern of activation in topographically organized areas), it may simply be epiphenomenal, not actually contributing to the information processing necessary to perform the task. If so, it is not surprising that little cerebral blood flow is associated with such visual image representations.

Second, there is a “figural imagery”—a type of imagery that relies on cortex situated in the inferior temporal lobes [this is different from the processing of spatial representations, as Mellet et al. (1996) have also suggested]. Figural imagery occurs only when a low-resolution topographic image is generated from the activation of stored representations of shapes and other object properties. Such representations arise in the posterior portions of inferior temporal cortex. There is some evidence in the literature that the region may, at least in monkey cortex, contain coarsely organized topographic areas (for an overview, see Felleman and Van Essen, 1991; see also DeYoe et al., 1994). The high-resolution components of the visual buffer need not be activated for such imagery to occur; however, DLPFC, the angular gyrus/Area 19, and areas that drive attentional processing should be recruited. These ideas fit well with results reported by Fletcher and colleagues (1995). In this PET experiment, participants were asked to remember and later recall concrete and abstract words. No activation was detected in MOC during recall of concrete words, which was assumed to induce imagery (e.g., see Paivio, 1971). However, the right superior temporal and fusiform gyri were activated (and activation was also observed in the left anterior cingulate and the precuneus). This task did not re-

quire high-resolution images; hence subjects may have formed only the minimal images needed to serve as memory prompts—which did not include details.

Levine, Warach, and Farah (1985) report a double dissociation that makes sense in light of this distinction between spatial representation and figural imagery. One patient who had damage to the parietal lobes was able to visualize objects but not spatial relations; in contrast, another patient had damage to the temporal lobes, and was able to mentally represent spatial relations but not objects.

Finally, we posit a third type of processing, which we call “depictive imagery.” This type of imagery, which relies on high-resolution representations in MOC, allows one to reorganize, reinterpret, or compare shapes. This type of imagery—the focus of this chapter—corresponds to what most people seem to mean when they say they are “seeing with the mind’s eye.”

Pure forms of these three types of processing may be relatively rare. We note, for instance, that the temporal/fusiform/lingual gyrus area seems to be activated in at least three of the studies that used spatial tasks (Charlot et al., 1992; Mellet et al., 1995; Roland and Friberg, 1985). Indeed, visual imagery may often be supplemented by linguistic representations, as well as other forms of imagery (e.g., motor and auditory).

Conclusions

Two major conclusions can be drawn from this review: First, many common neural processes underlie perception and depictive imagery. Second, the type of processing used depends on the task at hand. This last point is worth underlining: Many tasks in the neuroimaging imagery literature have not been specifically designed to tap a particular type of imagery processing. In fact, many of the tasks do not permit a clear appraisal of the type of processing that has occurred because they do not require subjects to produce a response. Given the complex nature of imagery and its component processes, it is clear that great care must be given to task design, with the aim of inducing a specific mode of operation of the system.

68 Cerebral Bases of Number Processing and Calculation

STANISLAS DEHAENE

ABSTRACT What is the cerebral basis of the human competence for mathematics? Cognitive neuroscientists have begun to address this issue in the small domain of elementary arithmetic. Chronometric experiments indicate that the human brain comprises an analogical representation of numbers, in which numerical quantities are internally manipulated as points on a mental “number line.” Neuropsychological studies of number processing indicate that this representation is distributed in the two hemispheres and point to inferior parietal cortex as its dominant site. The intraparietal network may provide a category-specific semantic representation of numerical quantities. Recent neuroimaging experiments confirm that this area is specifically activated when normal subjects manipulate numbers, regardless of the particular notations used to convey them.

Mental arithmetic is a basic ability of the human brain. In daily life, we encounter numbers in a wide variety of situations: We punch phone numbers, check our change, balance our bank accounts, take a train, check our driving speed; and, sometimes, we even plan or analyze scientific experiments. Of the content words of language, number words are among the most frequent: In English, we utter the word “one” once in every 70 words, and the word “two” once in every 600 words (Dehaene and Mehler, 1992; frequencies are comparable in other languages). Arguably, numbers are one of humanity’s most important cultural inventions, without which science or society as we know it would never have seen the light of day.

In recent years, experimental studies have begun to address an age-old puzzle—the origins of the human mind’s competence for mathematics. Using the methods of cognitive neuroscience, we can now ask what internal representations are used to manipulate numbers mentally, when and how they develop, and what brain areas are involved. Space precludes an exhaustive description of cognitive neuroscience studies of numeracy (but see Campbell, 1992; Dehaene, 1997; Dehaene and Cohen, 1995); rather, this chapter focuses on two issues—category specificity and modularity—issues of general inter-

est in cognitive neuroscience that have been addressed in the specific domain of numbers.

Category specificity refers to the hypothesis that different domains of knowledge—such as knowledge of animals, foods, actions, or objects—are subserved by dedicated mental processes, even by specific brain circuits. I have argued that the number domain provides a remarkable example of a biologically determined, category-specific domain of knowledge (Dehaene, Dehaene-Lambertz, and Cohen, 1998). Supporting evidence has accrued from multiple converging fields of research, including animal, infant, and adult human psychology, as well as lesion studies and brain imaging. This empirical evidence suggests that humans and animals possess a specific, biologically determined ability to attend to small numbers of objects or events in their environment. In humans, an internal representation of numerical quantities develops very rapidly in the first year of life; and, later in life, this representation underlies our ability to learn symbols for numbers and to perform simple calculations. It is specifically associated with neural circuitry in the inferior parietal lobule. Brain damage to these circuits can cause highly specific impairments in the representation and manipulation of numbers.

Arguably, then, biological evolution has internalized in our brains a dedicated cerebral system for number, comparable to the specialized cerebral devices that subserve color or stereo vision, auditory localization, or visuomotor transformations. Such a “number sense” is obviously useful to survival: It helps us make sense of a world composed, at the scale in which we live, largely of discrete objects forming sets whose combinations follow the rules of arithmetic.

The hypothesis of a dedicated brain system for quantity knowledge is superficially reminiscent of Gall and Spurzheim’s phrenology. In phrenological diagrams, all knowledge of numbers and mathematics was attributed to a specific brain convolution. Of course, the present claim is quite different. According to the hypothesis developed here, the internal representation of numerical quantities, which is putatively linked to cortical tissue within the intraparietal sulcus, is not the only repository

of arithmetic knowledge in our brains. Rather, it is assumed to be associated with a highly specific and limited mode of representation and manipulation of numbers, in the form of abstract quantities laid down on an analogical number line. Chronometric and neuropsychological studies indicate that the quantity representation is by no means the only internal code that humans use to manipulate numbers. Multiple representations, supported by a distributed cortical and subcortical network, underlie our ability to understand, produce, and mentally manipulate numbers in various formats, including arabic numerals (e.g., 32) and number words (“thirty-two”). Even extremely simple calculations, such as producing the result of $3 - 1$, involve the coordination of multiple brain areas within a complex cognitive architecture.

This is the second key concept of cognitive neuroscience to which the study of numerical cognition has strongly contributed—the *modularity of the cognitive architecture* for verbal and nonverbal processing. Numbers constitute a small domain of language, with its own lexicon of thirty-some words, its restricted syntax, and its easily defined semantics. Fine-grained studies of number production, comprehension, and calculation tasks have provided strong evidence for a modular organization at each of these levels.

Number processing in normal subjects

Moyer and Landauer (1967) first characterized the semantic representation of numerical quantities in human adults. They presented subjects with pairs of arabic digits, such as 3:4, and asked them to indicate which number was larger (or smaller). Response times and error rates were strikingly affected by number size and number distance (figure 68.1). As the numbers to be compared represented closer and closer quantities (e.g., 2:8 vs. 4:5), the subjects’ responses became increasingly slower and more error-prone. And when distance was kept constant, increasingly larger quantities again resulted in increasingly slower responses and larger error rates. Performance in comparing two numbers was determined by a Weber fraction, similar to that found when subjects have to compare physical parameters such as object size, line length, or tone height. Yet the number stimuli were presented in a symbolic notation, arabic numerals, whose surface form is largely arbitrary, conveying no information about number meaning. The distance effect suggested that subjects were converting the input numerals to an internal continuum, a mental “number line,” and were performing a psychophysical comparison on this internal representation rather than on the surface form of the numbers.

FIGURE 68.1 Distance effect: the amount of time it takes to decide which of two digits is larger is inversely related to the distance between them. Error rates show a similar trend. (Redrawn from Moyer and Landauer, 1967.)

Subsequent work largely confirmed the hypothesis of an internal conversion to a notation-independent analogical representation of quantity. Buckley and Gillman (1974) measured the time to compare numbers that were conveyed either by arabic numerals or by the numerosity of dot patterns. Performance was remarkably similar, driven in both cases by numerical distance and size effects. In later work, parallel performance patterns were found when subjects compared arabic numerals and number words in various languages (Dehaene, 1996; Tzeng and Wang, 1983). Obviously, the mental representation on which subjects based their comparative judgments abstracted away from the symbolic surface form of the numerals and encoded their quantitative meaning only. A continuous distance effect was found even when subjects compared two-digit numerals. The two-digit number comparison results indicated that subjects did not rely on a digit-by-digit analysis of decades and units, but rather performed a holistic evaluation of numerical quantity (Dehaene, Dupoux, and Mehler, 1990; Hinrichs, Yurko, and Hu, 1981).

Beyond the number comparison task, chronometric experiments with various number processing and calculation tasks have revealed ubiquitous number size and distance effects, indicating that the quantity representation plays a pivotal role in numerical cognition. For instance, in a same-different judgment task (Dehaene and Akhavein, 1995; Duncan and McFarland, 1980), subjects were shown a pair of numbers, such as 2:5, and asked to say whether or not the two numbers were the same, responding as fast as they could. Conceivably, subjects can respond on the basis of visual similarity alone. Thus, in one version of the task, subjects were actually encouraged to rely on such a superficial visual

analysis: They were asked to respond “different” to such pairs as “2:two,” in which the numbers are numerically identical but physically different. Nonetheless, response times were always affected by a distance effect. When subjects responded “different,” their responses were slower when the pair comprised two numbers that were numerically close (e.g., 2 and 3) than when it comprised two very different numbers (e.g., 2 and 8). Obviously, subjects could not prevent a mental conversion from digital symbols to the corresponding quantities.

Size and distance effects are also obvious when subjects calculate (Ashcraft and Battaglia, 1978). The time to perform an internal addition or multiplication operation varies considerably with the size of the numbers involved. Problems with small numbers, such as $2 + 3$ or 3×2 , are solved much faster than problems with large numbers such as $6 + 8$ or 6×8 . Of course, the greater practice we have with small arithmetic facts may contribute to this effect. The distance effect in calculation verification, however, cannot be explained by practice. When subjects are asked to verify whether an operation is true or false (e.g., $3 \times 6 = 72?$), responses are increasingly faster as the proposed result gets more distant from the true result of the operation. As with number comparison, number size and distance effects in calculation are similar whether numbers are presented as arabic digits or as number words, even though small but systematic differences seem to be found (for discussion, see Brysbaert, Fias, and Noel, 1998; Campbell, 1994; Noel, Fias, and Brysbaert, 1997; Vorberg and Blankenberger, 1993).

Hemispheric distribution of number processing abilities

While the existence of a mental representation of quantity has been known since the 1970s, cognitive neuropsychological studies have only recently begun to investigate the cerebral organization of number processing in the human brain. Perhaps the simplest question we can ask is, what is the hemispheric distribution of number processing abilities? Do both hemispheres have access to the quantity representation, and can both hemispheres calculate? This question has been examined in patients with callosal lesions. The corpus callosum is a large bundle of fibers that connects the two cerebral hemispheres. When it is lesioned or surgically sectioned, the cognitive abilities of each hemisphere can be assessed (Sperry, 1968). Numerical abilities were tested in a series of experiments initially performed with surgical split-brain cases (Gazzaniga and Hillyard, 1971; Gazzaniga and Smylie, 1984; Seymour, Reuter-Lorenz, and Gazzaniga, 1994). These results were recently replicated and extended in a study

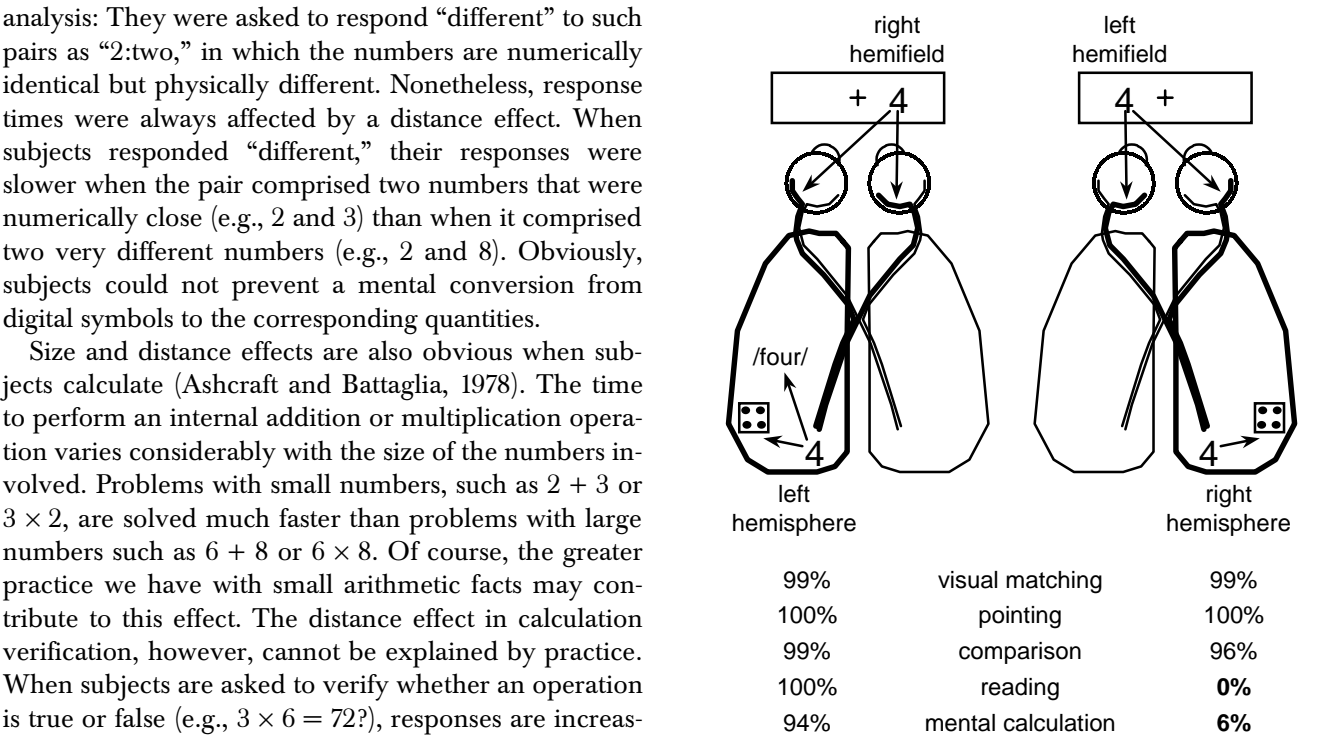

FIGURE 68.2 Split-brain patients provide evidence about the hemispheric distribution of number-processing abilities (Cohen and Dehaene, 1996). When digits are presented in the right visual hemifield of a split-brain patient, hence contacting only the left hemisphere, the patient can perform any number processing task with them, including visual recognition, pointing to the digit in a random array, larger–smaller comparison, reading, and calculation. Thus, the left hemisphere contains visual, verbal, and quantity representations of numbers. But when digits are presented in the left hemifield, hence contacting only the right hemisphere, the patient may still recognize, point to, or compare them, but fails to read them or calculate with them. Although the right hemisphere has access to visual and quantity representations, it seems to lack a verbal representation of numbers as well as procedures for exact calculation. (Data from patient JW; Gazzaniga and Smylie, 1984; Seymour, Reuter-Lorenz, and Gazzaniga, 1994.)

of a patient who suffered a posterior callosal lesion in adulthood (Cohen and Dehaene, 1996). In both sets of experiments, digits were flashed in either the left or the right hemifield, thus contacting only the contralateral hemisphere, and the patients were asked to perform number processing tasks of varying complexity with them (figure 68.2).

An important conclusion of these experiments is that both hemispheres can process digits and quantities. When two digits are presented simultaneously *within* the same hemifield, split-brain patients experience no difficulty deciding whether they are the same or different (while their disconnection renders them completely unable to compare two digits *across* the two hemifields). Hence, both hemispheres can analyze digit

shapes. Furthermore, both hemispheres can also point to the larger digit (or to the smaller), and both can classify digits or even two-digit numbers as larger or smaller than some reference. Hence, both hemispheres seem to possess a quantity representation of numbers.

The conclusions drawn from split-brain studies are sometimes questioned, either because some pathways for interhemispheric communication may remain functional, or because the patients may have had an abnormal cerebral organization to begin with. In the present case, however, both arguments can be refuted. First, it is true that the surgical-split cases (Gazzaniga and Smylie, 1984; Seymour, Reuter-Lorenz, and Gazzaniga, 1994) had an intact anterior commissure, and that the patient reported by Cohen and Dehaene (1996) had an infarct affecting only the posterior part of the corpus callosum. But the fact that the patients were at chance level when asked to compare arabic digits *across* the two hemifields offers clear evidence that the remaining pathways were not sufficient for the transmission of numerical information. Hence, their excellent performance when both stimuli were within the left hemifield cannot be attributed to transfer to the left hemisphere. The sharp dissociation between excellent within-hemifield performance and chance-level across-hemifield performance, indicating disrupted interhemispheric transmission, supports the hypothesis that both hemispheres can compare numbers. Second, while the patients studied by Gazzaniga and colleagues suffered from life-long neurological impairments, the patient studied by Cohen and Dehaene was neurologically normal prior to suffering a callosal lesion. Yet the number comparison results were identical in both cases. Hence, the ability of both hemispheres for number comparison does not seem to be an artifact of abnormal initial brain reorganization.

In only one callosal patient (to date) have the response times been recorded during the number comparison task and the distance effect analyzed (Cohen and Dehaene, 1996). A normal distance effect was observed in both hemispheres, with no significant difference in effect size between the two hemispheres. This suggests that the quantity representations of the left and right hemispheres may have similar characteristics. However, more evidence is needed before this point can be firmly accepted.

There are, however, at least two striking differences between the numerical abilities of the left and the right hemispheres. First, digits presented to the left hemisphere can be named normally by the patients, but digits presented to the right hemisphere cannot. This is in keeping with the well-known lateralization of speech production abilities to the left hemisphere. Second, split-brain patients can calculate only with digits presented to

their left hemisphere. When digits are presented to their right hemisphere, the patients fail with operations as simple as adding 2, multiplying by 3, subtracting from 10, or dividing by 2. This is the case even when they merely have to point to the correct result among several possible results, or to indicate nonverbally whether a proposed result is correct or not. The only calculation ability that seems to be available to an isolated right hemisphere, at least occasionally, is approximation. A patient might not be able to decide whether $2 + 2$ makes 4 or 5, but might still easily notice that $2 + 2$ cannot make 9 (Cohen and Dehaene, 1996; Dehaene and Cohen, 1991).

Modular dissociations in brain-lesioned patients

Detailed single-case studies of patients with various cerebral lesions have indicated that the fractionation of calculation skills in neuropsychological cases is much greater than that seen in split-brain cases alone. The number processing skills of a normally educated adult include the ability to

- read, write, produce, or comprehend numerals in both arabic (e.g., 12) and verbal (“twelve”) formats, thus implying both lexical (single-word) and syntactic (multiple-word) processes;

- convert numbers in these various formats to internal quantities, and vice-versa;

- compute single-digit addition, subtraction, multiplication, and division operations;

- coordinate several such elementary operations to solve a complex, multidigit arithmetic problem.

Most if not all of these abilities have been found to dissociate in brain-lesioned patients, often in a highly specific manner, indicating that there must be partially specific cerebral circuits associated with each of them.

As a detailed example, let us consider the case of patient HY (McCloskey, Sokol, and Goodman, 1986). When attempting to read an arabic numeral aloud, HY often erred, for instance, reading 5 as “seven” and 29 as “forty-nine.” A careful analysis indicated that reading errors stemmed from a highly restricted impairment, affecting only one particular cognitive component of the processing chain that converts written arabic numerals into spoken words. First, HY could still decide which of two arabic numerals was the largest. She could also match an arabic digit to a written number word, verify written calculations, or select a number of poker chips corresponding to a given arabic numerals. Thus, identification of digits and access to quantity information were preserved. This narrowed down the reading deficit to an impairment at the level of producing spoken words. In-

deed, McCloskey and his colleagues showed that, in a variety of tasks, HY was much more impaired when he had to produce the numerical answers aloud than when he had to write them down as arabic digits. For instance, when asked the number of eggs in a dozen, HY wrote 12 but said "sixteen."

A careful analysis of HY's number production errors revealed strong regularities. The vast majority of errors were substitutions of one number word for another, keeping the grammatical structure of the number intact. Not all substitutions were equally permissible. When the number fell between 1 and 9, so did HY's erroneous response. The categories of teens (10 to 19) and decades (20 to 90) was also respected. In the final analysis, the deficit could be explained by a highly selective impairment in selecting the appropriate number word in the output lexicon. When reading "15," for instance, the patient prepared to read aloud the fifth element of the teens category (eleven, twelve, thirteen, fourteen, *fifteen*), but he mistakenly selected, say, the eighth element *eighteen* instead. Only minor details of the word substitutions remained unexplained by this hypothesis (Campbell and Clark, 1988; Sokol, Goodman-Schulman, and McCloskey, 1989).

A wide variety of similar highly specific deficits of number processing have now been reported (Cipolotti and Butterworth, 1995; Cipolotti, Warrington, and Butterworth, 1995; Dehaene and Cohen, 1995; McCloskey, 1992). Most importantly, at virtually all levels of processing, dissociations have been observed between numbers and the rest of language, suggesting an amazing degree of modularity in the human brain. For instance, at the visual identification level, pure alexic patients who fail to read words often show a largely preserved ability to read and process digits (Cohen and Dehaene, 1995; Déjerine, 1891, 1892). Conversely, a case of impaired number reading with preserved word reading is on record (Cipolotti, Warrington, and Butterworth, 1995). In the writing domain, severe agraphia and alexia may be accompanied by a fully preserved ability to write and read arabic numbers (Anderson, Damasio, and Damasio, 1990). Finally, within the speech production system, patients who suffer from random phoneme substitutions, resulting in the production of an incomprehensible jargon, may produce jargon-free number words (Cohen, Verstichel, and Dehaene, 1998; Geschwind, 1965).

Selective impairments of the quantity representation

The aforementioned deficits concerned the processing of numerical symbols. But do some cases qualify as selective impairments of the semantic quantity representation

of numbers? Laurent Cohen and I have proposed that patients with inferior parietal lesions and Gerstmann-type acalculia suffer from a category-specific impairment of the semantic representation and manipulation of numerical quantities (Dehaene and Cohen, 1995, 1997). From the beginning of this century, it has been known that parietal lesions, usually in the dominant hemisphere, can cause calculation deficits. Gerstmann (1940) reported the frequent co-occurrence of agraphia, acalculia, finger agnosia, and left-right confusion in parietal cases, a tetrad of deficits referred to as Gerstmann's syndrome (although the elements of the syndrome are now known to be dissociable; see Benton, 1992). The lesions that cause acalculia of the Gerstmann type are typically centered on the portion of the intraparietal sulcus that sits immediately behind the angular gyrus (Brodmann's area 39; see figure 68.3). In many cases, the deficit can be extremely incapacitating. Patients may fail to compute operations as simple as $2 + 2$, $3 - 1$, or 3×9 . Several characteristics indicate that the deficit arises at a rather abstract level of processing. First, patients may remain fully able to comprehend and to produce numbers in all formats. Second, they show the same calculation difficulties whether the problem is presented to them visually or auditorily, and whether they have to respond verbally or in writing, or even merely have to decide whether a proposed operation is true or false. Thus, the calculation deficit is not due to an inability to identify the numbers or to produce the operation result.

Cohen and I, however, also believe that the patients' impairment is not best described as a specific deficit of calculation only ("anarithmetia" or "acalculia proper"). On the one hand, some calculation processes may remain preserved. Patient MAR, for instance (Dehaene and Cohen, 1997), remained able to retrieve simple multiplication results, such as $2 \times 3 = 6$ or $3 \times 9 = 27$, which he knew by rote. He was very specifically impaired with calculations that were not stored in rote memory and required an internal quantity manipulation, even if it was as simple as $3 - 1$ (he stated that this equaled 7). On the other hand, tasks that require a quantitative understanding of numbers, but are not typically associated with calculation per se, can be impaired in Gerstmann's syndrome patients. Patient MAR could not decide which number fell between 2 and 4 (number bisection task), even though he knew what letter fell between B and D, or what month fell between February and April. MAR also exhibited a discrete difficulty in number comparison, occasionally stating, for instance, that 5 was larger than 6.

The latter deficit suggests that MAR's understanding of the number line was impaired. Indeed, Cohen and I have suggested that inferior parietal cortex holds the

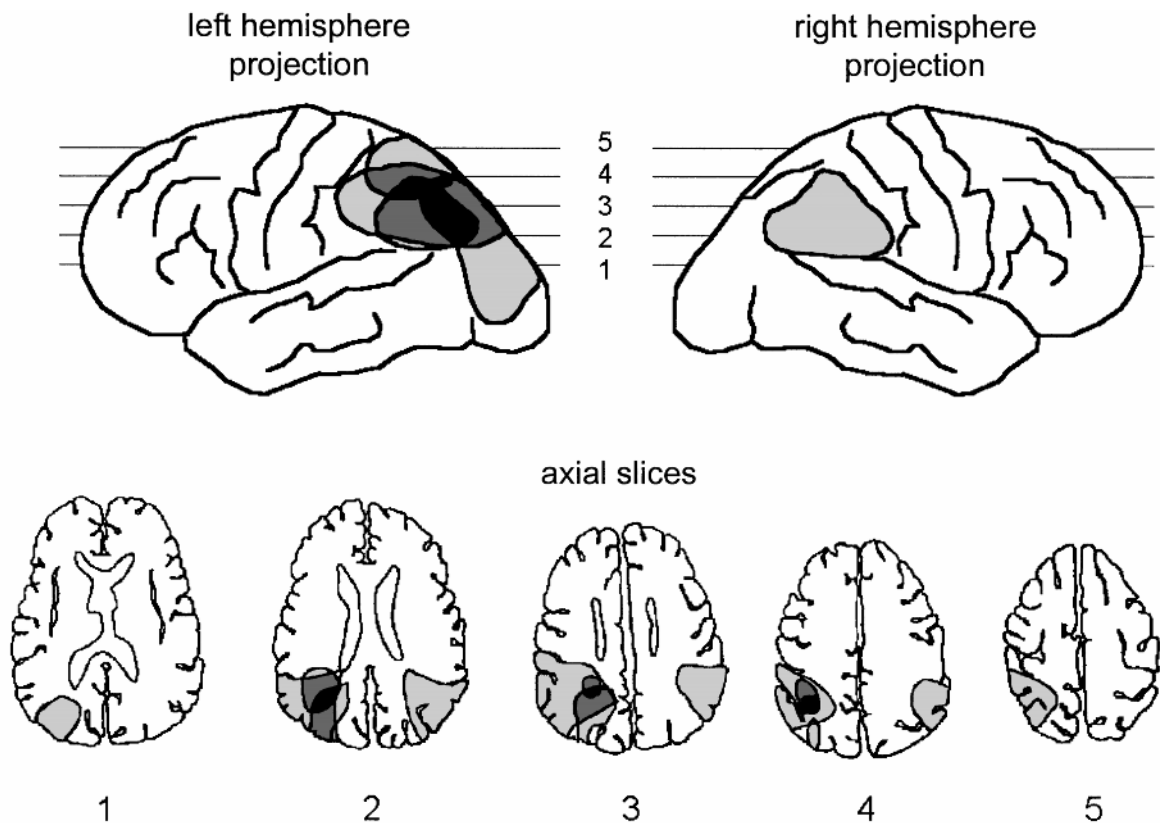

FIGURE 68.3 Overlapping lesions of five patients with Gerstmann's syndrome. All patients showed severe deficits in the comprehension and mental manipulation of numbers. The le-

sions overlap deep in the inferior lobule, in the vicinity of the intraparietal sulcus. (Redrawn from Dehaene and Cohen, 1997; Takayama et al., 1994.)

internal analogical representation of numerical quantities. Damage to this region causes calculation deficits only if the requested calculations call for internal manipulation of quantities, and not if the task merely involves the retrieval of rote arithmetic facts from verbal memory. Typically, then, subtraction and number bisection are severely impaired, while simple multiplication may be relatively preserved. The fact that interval bisection is affected only in the number domain, but not in the domain of the alphabet, months, or days of week, gives direct evidence that the deficit can be category-specific and not just task-specific.

A simple model of number processing circuits

Based on the variety of number-processing deficits that can be observed in patients, Laurent Cohen and I have proposed a tentative model of the cerebral circuits implicated in calculation and number processing: the *triple-code model* (see figure 68.4; Dehaene, 1992; Dehaene and Cohen, 1995). Initially developed as a purely cognitive model of the different types of representations involved in various number-processing tasks, this model also aims

to explain chronometric data from normal subjects (Dehaene, 1992). A later version (Dehaene and Cohen, 1995) made specific proposals as to the putative cerebral substrates of these representations.

Functionally, the model rests on three fundamental hypotheses:

1. Numerical information can be manipulated mentally in three formats: an analogical representation of quantities, in which numbers are represented as distributions of activation on the number line; a verbal format, in which numbers are represented as strings of words (e.g., thirty-seven); and a visual Arabic number form representation, in which numbers are represented as a string of digits (e.g., 37).

2. Transcoding procedures allow information to be translated directly from one code to the other. For instance, the model supposes that one can mentally convert an arabic digit to the corresponding number word (from 3 to three) nonsemantically, without passing through the semantic representation of the quantity three. This hypothesis distinguishes the triple-code model from other modular models of number processing (e.g., McCloskey, Macaruso, and Whetstone, 1992)

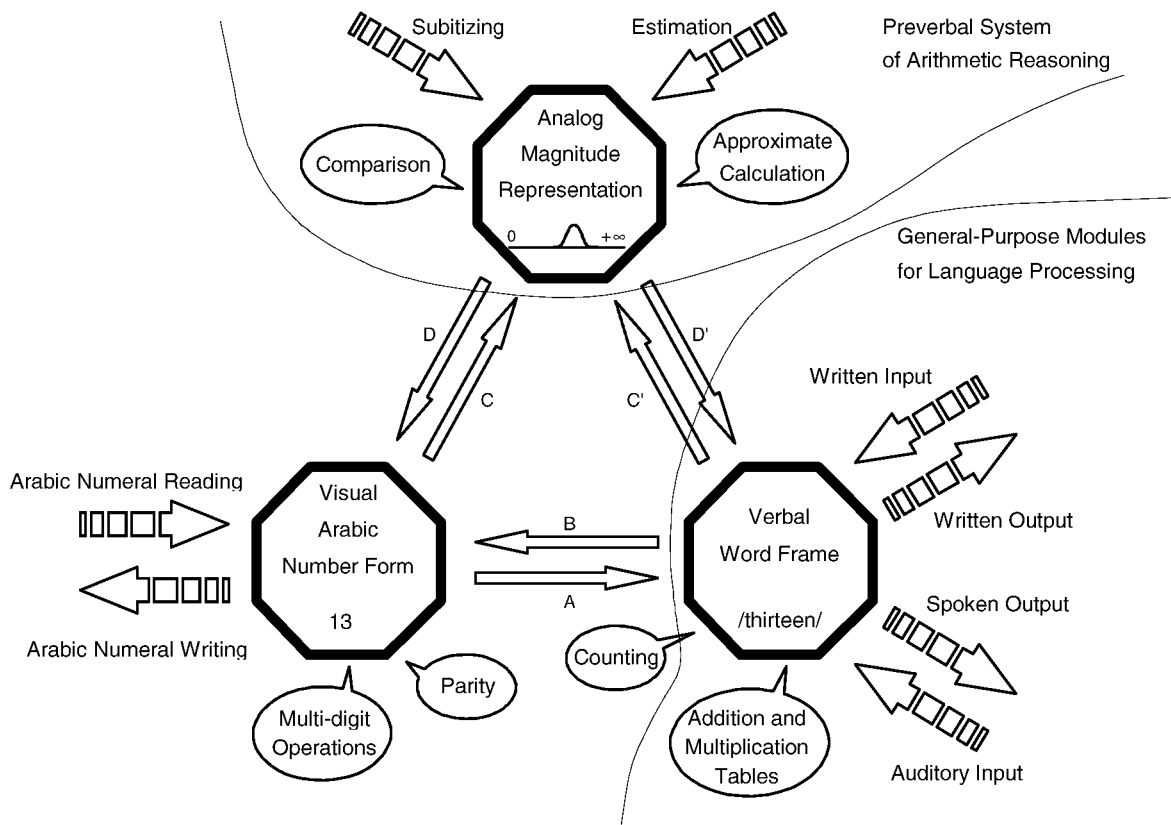

FIGURE 68.4 Functional architecture of the triple-code model of number processing. The three cardinal representations of numbers are represented by octagons. Direct input and output pathways to and from these representations are represented by

thick arrows, while thin arrows represent the six possible transcoding pathways that link them. Specific processes putatively attached to a given level of representation are denoted by balloons. (Redrawn from Dehaene, 1992.)

and is more in line with multiple-route models of word processing. Recently, this aspect of the model has received strong support from the observation of patients who cannot convert directly from arabic to verbal numerals (e.g., cannot read arabic digits aloud), but can still convert back-and-forth between these representations and the corresponding quantities (Cipolotti and Butterworth, 1995; Cohen and Dehaene, 1995).

3. Each number-processing task is assumed to rest on a fixed set of input and output codes. For instance, number comparison is postulated to rely on numbers coded as quantities on the number line. Likewise, the model postulates that multiplication tables are memorized as verbal associations between numbers represented as a string of words; that subtraction, an operation that is not memorized by rote verbal learning, calls heavily on the quantity representation; and that multidigit operations are often performed mentally using the visual arabic code and a spatially laid-out representation of the aligned digits.

Neuropsychological observations have enabled us to flesh out the model and to associate tentative anatomical

circuits to each function. Cohen and I speculate that the inferior occipitotemporal sectors of both hemispheres are involved in the visual identification processes that give rise to the arabic number form; that the left perisylvian areas are implicated in the verbal representations of numbers (as with any other string of words); and, most crucially, that the inferior parietal areas of both hemispheres are involved in the analogical quantity representation.

Note that the redundant representation of the visual and quantity codes in the left and right hemispheres can explain why, in callosal patients, number comparison remains feasible by both hemispheres (Cohen and Dehaene, 1996; Seymour, Reuter-Lorenz, and Gazzaniga, 1994). This bilaterality assumption does seem to raise a problem for interpreting acalculia cases, however. If there is a bilateral quantity representation, why does a *unilateral* inferior parietal lesion suffice to impair quantity manipulation in Gerstmann syndrome patients? Lesion data clearly indicate that, although the right hemisphere contains a representation of quantity (and although the right inferior parietal cortex is strongly activated during calculation), only a left-lateralized lesion, in

FIGURE 68.5 A schematic diagram of the anatomical substrates of the triple-code model of number processing. (Redrawn from Dehaene and Cohen, 1995.)

subjects with normal hemispheric dominance, causes acalculia of the Gerstmann type.

In spite of the superficial paradox, the triple-code model can explain this result. According to the model, only the left hemisphere has access to the verbal code and to the calculation abilities that depend on it. In the case of a unilateral left inferior parietal lesion, the model therefore predicts that the right-hemispheric parietal quantity representation, although intact, will be functionally disconnected from the left-hemispheric language system (see figure 68.5). Hence, such patients may remain largely able to compare number and perform other manipulations of pure quantities (this was the case with patient MAR, who was largely above chance in number comparison). Yet, according to the model, they are not able to use this quantity knowledge to guide arithmetic fact retrieval and number production, hence their striking deficit in simple arithmetic. The same argument also explains why the right hemisphere of callosal patients cannot read numbers aloud nor calculate with them. Only further research will tell whether this account of the special role of left parietal lesions in acalculia cases is valid. It should also help us grasp a better understanding of the respective roles of the left and right inferior parietal areas in number processing.

Brain imaging of calculation

Functional brain-imaging techniques now provide new tests of the organization of cognitive processes, including calculation processes. In itself, information about cerebral localization is not particularly interesting to cognitive scientists. Once a specific brain area has been

localized, however, it becomes possible to ask some fruitful questions: What are the parameters that make it more or less active? What tasks is it responsive to? And what aspects of the stimulus, task, or response do *not* affect its state of activity? With dynamic methods such as electro- or magnetoencephalography, it is also possible to record how quickly and for how long a region activates. In all these respects, the triple-code model makes specific predictions. Most critically, it predicts that the left and right inferior parietal areas should be active during various quantitative number-processing tasks, and that their activation should depend purely on quantitative parameters such as number size and numerical distance, but not on input or output modality nor on the notation used for numbers.

Roland and Friberg (1985) were the first to monitor blood flow changes during calculation as opposed to rest. When subjects repeatedly subtracted 3 from a given number, activation increased bilaterally in inferior parietal and prefrontal cortex. These locations have been confirmed using fMRI (Burbaud et al., 1995; Rueckert et al., 1996). Because the serial subtraction task imposes a heavy load on working memory, it was not clear whether any of these activations were specifically related to number processing. However, experiments using simpler tasks have confirmed that the inferior parietal area seems to play a specific role involved in number processing. In a positron emission tomography study of multiplication and comparison of digit pairs, with little or no working memory component, my colleagues and I again found bilateral parietal activation confined to the intraparietal region (Dehaene et al., 1996). This confirmed results obtained with a coarser resolution EEG method (Inouye et al., 1993) as well as

with single-unit recordings in neurological patients (Abdullaev and Melnichuk, 1996).

While these studies indicate that the left and right inferior parietal areas are active and presumably play an important role in calculation tasks, they do not establish the exact nature of their contribution. The triple-code model, however, makes the specific prediction that the inferior parietal cortex activation reflects the operation of an abstract quantity system independent of input and output modalities. Recently, my colleagues and I have begun to test this prediction.

In one study, we used high-density recordings of event-related potentials (ERPs) during a number comparison task to study the cerebral basis of the distance effect. An additive-factor design was used in which three factors were varied: number notation (arabic or verbal), numerical distance (close or far pairs), and response hand (right or left). The results revealed that inferior parietal activity was modulated by the numerical distance separating the numbers to be compared, but not by the notation used to present them (Dehaene et al., 1996). Notation did have a significant effect on the N1 wave, around 150 milliseconds after the visual presentation of the stimuli, indicating bilateral processing for arabic digits, but unilateral left-hemispheric processing for visual number words (in agreement with the triple-code model). By about 200 ms, however, ERPs were dominated by a parietal distance effect with a significant lateralization to the right, and without further influence of notation. Dipole models indicated that the scalp-recorded distance effect could be modeled by two bilateral dipoles located deep within the inferior parietal lobule, with the right-hemispheric dipole showing stronger activation than the left. The response hand effect, which emerged as early as 250 ms after the stimulus, provided an upper bound on the duration of the numerical comparison process.

A similar ERP study of number multiplication (Kiefer and Dehaene, 1997) showed that inferior parietal activity lasts longer during multiplication of two large digits than during multiplication of two small digits—again, regardless of the modality of presentation of the operands (auditory or visual). The main difference with the previous study of number comparison was that the ERP effects, though always bilateral, were stronger over the left inferior parietal area during multiplication, but stronger over the right parietal area during number comparison.

Recently, my colleagues and I replicated this modulation by task demands using fMRI (Chochon et al., 1999). We alternated 36-second blocks during which either single letters or single digits were flashed in the center of a screen. During the letter blocks, the subjects

mentally named the letters. This served as a control for the various arithmetic tasks used during the digit blocks. On different runs, subjects were asked to name the digits, to compare them with 5, to multiply them by 3, or to subtract them from 11. In all subjects, fMRI identified a bilateral network that was very clearly pinpointed to the banks of the middle segment of the intraparietal sulcus (figure 68.6), in a location in excellent agreement with the result of lesion studies in Gerstmann's syndrome (figure 68.3). Importantly, however, the size and lateralization of this parietal activation was modulated by task demands. Relative to letter reading, digit comparison yielded greater activity in the right inferior parietal area, multiplication greater activity in the left parietal area, and subtraction a bilateral increase. In agreement with the hypothesis of a nonsemantic direct naming route, however, digit naming in itself did not significantly activate the parietal areas, although a small activation of the right intraparietal cortex was occasionally seen in some subjects.

Number: A biological determined category of knowledge?

In summary, number processing constitutes a remarkable example of the power of the cognitive neuroscience approach, in which a combination of methodologies borrowed from cognitive psychology, neuropsychology, and brain imaging is brought to bear on a single problem. Based on the converging evidence just reviewed, the following working hypotheses can be formulated:

1. The human brain contains an analogical representation of numerical quantities, which can be likened to a mental "number line." This representation is independent of, and common to, the multiple input and output notation systems we use to communicate numbers, such as words or arabic digits. It is subject to distance and magnitude effects.
2. Both the left and the right hemisphere have access to the mental representation of numerical quantity.
3. Lesions of the intraparietal cortex in the dominant hemisphere yield a specific impairment in the mental manipulation of quantities, particularly evident in subtraction and number bisection tasks.
4. The left and right intraparietal cortices are active when normal subjects perform simple calculation tasks. The strength, duration, and lateralization of their activation depends on the nature and difficulty of the operation involved, which in turn is related to the size and numerical distance of the numbers involved. It does not, however, depend on the modality or notation in which the numbers are presented.

FIGURE 68.6 Bilateral activations of the intraparietal sulcus, postcentral sulcus, and prefrontal areas during single-digit subtraction in a single subject. (Data from Chochon et al., 1999.)

Empirical findings lend support to the hypothesis that some neural circuits within intraparietal cortex include a partially prewired, biologically determined representation of numerical quantities, a category-specific system innately biased toward acquiring and manipulation information about numbers. In that respect, several details of the data should be mentioned, although space precludes a more thorough discussion of these topics (see Dehaene, 1997; Dehaene, Dehaene-Lambertz, and Cohen, 1998; Gallistel and Gelman, 1992). First, nonhuman primates, as well as other species such as rats, pigeons, or dolphins, exhibit remarkable capacities for extracting and manipulating numerosities. Furthermore, like humans, they are sensitive to numerical distance and size effects, suggesting that their numerical abilities may be phylogenetically related to ours, and are not merely superficially analogous. This supports the idea that our brains may have incorporated a dedicated representation of numbers in the course of evolution. Second, preverbal human infants also show remarkable number-processing abilities prior to schooling, supporting the autonomous emergence of a dedicated “number sense” during early development. Third, there are cases of developmental calculation deficits—highly specific, modular deficits of number processing, plausibly related to early brain damage—that leave intact other semantic

processing abilities. This supports the existence of a dedicated brain circuit specifically prepared to acquire elementary arithmetic and whose lesion largely abolishes the acquisition of numeracy. Fourth, the specific role of the intraparietal cortex in calculation in adult humans seems to be universal and largely independent of the culture, education, or number notation system acquired by the individual. Hence, acalculia in the context of Gerstmann’s syndrome is found with similar lesion sites in patients from various countries and cultures, and intraparietal activations during calculation have been seen in subjects from various countries.

While this converging evidence certainly supports the notion of a dedicated, category-specific cerebral circuit for number sense, the final validation of this concept will have to await the acquisition of important new data. There are several loose ends to the demonstration that intraparietal cortex is the seat of a specialized, biologically determined representation of number. It seems, therefore, quite appropriate that this chapter should end with a list of open questions for further research to address:

- Is a specific region of the human intraparietal cortex entirely specialized for number processing, or is there some overlap with areas involved in spatial representa-

tion, attentional displacements, hand movements, and/or mental rotation tasks?

- Is a homolog of human intraparietal cortex active in animals during number processing tasks? If so, what is its architecture and what are its single-cell properties?

- Is intraparietal cortex active during infancy and does it underlie infants' abilities for elementary arithmetic?

- How are the cerebral circuits for number processing modified as children acquire the formal rules of arithmetic? How is numerical expertise reflected in the organization of intraparietal cortex?

We can hope that in the upcoming years we will begin to answer these questions, and hence begin to understand how the human brain gives rise to what is perhaps its most extraordinary feat—mathematics.

69 Cerebellar Contributions to Cognition and Imagery

RICHARD B. IVRY AND JULIE A. FIEZ

ABSTRACT The cerebellum has traditionally been viewed as an integral part of the motor system. However, recent anatomical, neuropsychological, and neuroimaging work indicates that this subcortical structure may contribute to cognitive processing in a substantive manner. A number of different theoretical frameworks for understanding cerebellar involvement in cognition have been developed. These include functional hypotheses that have emphasized diverse ideas ranging from an essential role for the cerebellum in the control of attention, error detection and learning, internal control of timing, or covert action and imagery. This chapter outlines the principal sources of motivation for this mini-revolution and reviews the evidence in support of these theoretical conjectures.

A decade ago, the inclusion of a chapter on the cerebellum in a section on “Thought and Imagery” would have seemed preposterous. The cerebellum has traditionally been viewed as an integral part of the motor system, with functional descriptions referring to its role in the coordination of skilled movement, motor learning, and the control of balance. Cognitive psychologists have tended to overlook the study of such processes, perhaps because movements are assumed to be built on reflexive units, subserved by dedicated systems that involve few of the kinds of representational capabilities characteristic of cognitive systems. Nonetheless, action systems have recently garnered increased interest in cognitive psychology as researchers recognize that the essence of a complex processing system is to allow an organism to act in a flexible and efficient manner.

As part of these developments, interest in the cerebellum has exploded in the past decade. Much of the work here continues in the motor tradition, especially that in the computational and neurophysiological literatures. However, the view that the domain of cerebellar function can be understood within the relatively narrow framework of motor control and learning is undergoing some serious challenges. Some of the new hypotheses are extensions of functional accounts of the cerebellum’s role in motor control, based on the idea that certain

computations originally evolved for controlling action may have been co-opted into other contexts. Other hypotheses are divorced from the motor domain, building on the idea that this massive structure may contribute in a heterogeneous manner to a number of distinct cognitive systems.

Here, we review the evidence motivating this revolution and provide an overview of the different functional hypotheses proposed to account for how the cerebellum might contribute to the executive operations of a sophisticated cognitive system. Given that this paradigm shift is truly in its infancy, our evaluation of the evidence is tempered. We seek to maintain the appropriate level of skepticism demanded by science while avoiding the temptation to suffocate, prematurely, the ideas that may provide the seeds for novel conceptualizations of the relationship between the brain and behavior.

Evidence indicating a role for the cerebellum in higher cognition

The hypothesis that the cerebellum might be involved in higher level cognition did not spring, Athene-like, from the head of Zeus. Over the past century, there have been scattered proposals suggesting that a strictly motoric view might be limited (see review in Schmahmann, 1997). Some of these early hypotheses were inspired by Piagetian ideas emphasizing the link between action and knowledge; others derived from observations regarding the link between the cerebellum and certain autonomic functions. These ideas, however, failed to take hold, in part because the experimental evidence in support of these somewhat radical notions was minimal at best. Moreover, simple clinical observation was sure to exert a powerful bias: Patients or animals with cerebellar lesions exhibit pronounced deficits in motor control. Any coexisting disorders of autonomic function, emotion, or higher mental thought were clearly minimal in contrast to the severe problems in coordination.

New perspectives on cerebellar function are closely linked to the emergence of cognitive neuroscience as an interdisciplinary enterprise. In this section, we briefly

FIGURE 69.1 Schematic drawing of the monkey cerebellum indicating the relative proportion of the three major subdivisions—the archicerebellum, the paleocerebellum, and the neo-

review some of the anatomical, behavioral, and imaging findings that have motivated researchers to propose extensions of the domain of cerebellar function beyond motor control. These results set the stage for the next section, in which we evaluate various functional hypotheses of how the cerebellum may contribute to cognition.

ANATOMICAL CONSIDERATIONS The cerebellum has long fascinated neuroanatomists. While it constitutes about 10% of the total mass of the central nervous system in humans, it contains more than 50% of all the neurons. The cerebellar cortex is traditionally divided into three subregions—the archicerebellum, the paleocerebellum, and the neocerebellum (figure 69.1). The latter region, especially the more lateral zones that constitute the cerebellar hemispheres, would seem to provide the essential anatomical substrate for influencing cognition. This region has undergone tremendous expansion in primates (Leiner, Leiner, and Dow, 1986). The primary input to the cerebellar hemispheres comes from the pontine nuclei. Labeling methods demonstrate that these brainstem nuclei are innervated by both ascending and descending fibers. Of particular interest is the fact that the descending corticopontine fibers not only originate in motor and premotor areas, but are also found in parietal, temporal, and prefrontal cortices (Schmahmann and Pandya, 1997).

The output from the cerebellum also suggests that this structure is part of a network that extends beyond the

cerebellum. The neocerebellum has undergone tremendous expansion in primates, paralleling similar evolutionary developments in the frontal lobes.

“motor” system. All cerebellar output originates in the deep cerebellar nuclei. Most prominent in humans, indeed, accounting for more than 90% of all nuclear cells, is the dentate nucleus. Using a transneuronal retrograde tracing technique, Middleton and Strick (1994, 1997) demonstrated that the output from the dentate nuclei is linked with motor, premotor, and prefrontal cortex via segregated thalamic relays. Thus, the cerebellum is not just receiving input from distributed cortical regions; it also has the prerequisite connections for influencing the kinds of functions associated with prefrontal cortex. It should be noted that there have been no systematic quantitative studies comparing the distribution of cerebellar projections to motor, premotor, and prefrontal areas, and little effort has been made to ascertain whether the cerebellum projects to more medial aspects of prefrontal cortex. The emphasis to date has been on establishing the existence of cerebello-prefrontal pathways.

Studies of the neuropathology associated with certain psychiatric disorders also suggest a cerebellar role in cognition and emotion. In vivo structural MR studies have shown that cerebellar pathology, especially in neocerebellar regions, appears to be a consistent feature of autism (Courchesne, Townsend, and Saitoh, 1994; but see Bauman, Filipek, and Kemper, 1997), as post-mortem histological analyses suggest (Ritvo et al., 1986). More recent studies have also shown pathology in non-cerebellar structures, including the brainstem, limbic re-

gions, the corpus callosum, and the parietal lobes (see Courchesne, 1997). Thus, the question as to whether there is a causal link between the cerebellar pathology and autism remains open. Nonetheless, the fact that cerebellar anatomy is consistently abnormal in autism is provocative, given that coordination problems are not generally associated with this disorder. There are also reports of cerebellar abnormalities in the brains of schizophrenics (Katsetos, Hyde, and Herman, 1997).

PERFORMANCE OF CEREBELLAR PATIENTS ON NEUROPSYCHOLOGICAL TESTS A more direct assay on the role of the cerebellum in cognition comes from neuropsychological studies of patients with either focal or diffuse cerebellar damage. The evidence is mixed on the basis of assessments using standardized batteries from clinical neuropsychology (see review by Daum and Ackermann, 1997). In general, patients with lesions restricted to the cerebellum perform within the normal range on IQ tests. It is difficult to compare their performance to normal subjects since the latter are selected in order to match the patients in terms of IQ. Nonetheless, group studies from three different laboratories have found that the patients score in the normal range when given either the complete Wechsler Adult Intelligence Scale or subtests of this instrument (Daum et al., 1993; Dimitrov et al., 1996; Mangels, Ivry, and Shimizu, 1998).

Daum and colleagues (1993) report one of the most comprehensive studies to date. Their study included nineteen patients: In thirteen patients the damage was restricted to the cerebellum, and in six the damage extended to brainstem structures (e.g., olivopontocerebellar atrophy). The patients were given an extensive battery of tests designed to assess frontal lobe function, verbal memory, and visuospatial memory. The performance of the cerebellar-only group was comparable to that of age-, IQ-, and mood-matched control subjects. In contrast, the patients with cerebellar plus brainstem damage performed more poorly than the control and cerebellar-only groups on the various measures. This pattern is evident in related studies (Appollonio et al., 1993). Performance on neuropsychological tests appears to decline as atrophic processes become more advanced, and may well reflect the involvement of noncerebellar structures (Kish et al., 1994).

A number of researchers have borrowed experimental tasks from cognitive psychology to explore specific domains of performance by patients with cerebellar lesions. These studies have shown that these patients may perform poorly even when the tasks minimize motor requirements. For instance, cerebellar patients have difficulty in generating a list of words that begin with a target letter (Appollonio et al., 1993; Mangels, Ivry, and

Shimizu, 1998) or in learning arbitrary associations between different semantic categories (Bracke-Tolkmitt et al., 1989). Results from such testing have been used to provide support for various functional theories of the cerebellum, as we discuss in greater detail below. It should be noted that the interpretation of the findings is often a matter of debate, since many of the tasks involve a number of component operations and similar abnormal performance can be observed in a variety of groups with cortical lesions (Daum and Ackermann, 1997). For instance, impaired performance on tasks associated with the frontal lobes may not be directly related to cerebellar function, but rather may be secondary to changes in cortical processing that arise indirectly from cerebellar pathology.

NEUROIMAGING Neuroimaging data have probably provided the greatest impetus for the cerebellar cognitive revolution. A large body of literature has convincingly demonstrated that changes in metabolic activity in the cerebellum are not simply correlated with the extent of overt motor behavior (for a review of visual studies, see Shulman et al., 1997). Indeed, it is almost harder to find a study using subtractive logic that does not identify a cerebellar locus of activity than one in which the cerebellum appears silent.

Consider the widely cited language studies of Petersen and colleagues (Petersen et al., 1989; Raichle et al., 1994). One contrast sought to identify neural structures associated with the analysis of semantics. On each trial, subjects were presented with a single word, a common noun. In the control condition, they simply had to read the stimulus word aloud. In the experimental condition, they were required to generate a semantic associate of the stimulus word, in particular, a verb associate. For example, for a target word *apple*, an appropriate response might be "peel" or "throw" or "eat." Thus, the perceptual demands were identical in the two conditions—read a single word; and, motorically, the subjects articulated a single word on each trial. Nonetheless, activation in the right cerebellar cortex was significantly greater in the generate condition than in the control condition.

Initially, the cerebellar activation sites were reported with relatively little discussion, reflecting the fact that the existing literature offered scant basis for interpreting these results. But as these serendipitous results turned up across a range of imaging studies, they began to invite attention. Several recent studies have focused specifically on the cerebellum, with a view to identifying task domains that produce signal changes in this subcortical structure. For example, Kim, Ugurbil, and Strick (1994) used a 4-tesla magnet in a functional MRI study to focus on activation in the dentate nucleus. This structure

showed greater activation during a difficult problem-solving task, even though the subjects were actually producing less overt movement in this condition compared to a control condition involving an easy problem-solving task. Other fMRI researchers have hypothesized that cerebellar activation may be related to attention shifting (Allen et al., 1997), memory rehearsal (Desmond et al., 1997), and sensory exploration (Gao et al., 1996).

Functional hypotheses

While the evidence just reviewed is intriguing, the cognitive neuroscience community has yet to reach consensus on how (and even if) the cerebellum contributes to higher cognition. Many of the behavioral tasks used in neuropsychological studies are quite complex and the observed deficits are open to a variety of interpretations. Neuroimaging techniques such as PET and fMRI offer powerful tools for addressing questions of anatomy but, to date, have been of limited value for developing functional accounts of the metabolic changes. In this section, we review some of the functional hypotheses that have been proposed for how the cerebellum contributes to cognition. Our review here is selective. Our criterion was twofold. First, we focus on those that have been articulated with sufficient clarity to allow empirical evaluation. Second, in keeping with the spirit of this section of the volume, we emphasize hypotheses that are most relevant to the study of thought and imagery.

MENTAL COORDINATION AND THE CONTROL OF ATTENTION Theories of the cerebellum and cognition are generally grounded in the belief that, over the course of evolution, the functional capabilities of this subcortical structure have come to extend beyond a more restricted motor domain. In their seminal paper, Leiner, Leiner, and Dow (1986) offered the conjecture that the highly evolved cerebellum of primates plays a central role in mental coordination, analogous to its role in motor coordination. The idea here, although somewhat vague, is that the cerebellum ensures that processing in distributed regions of the central nervous system is coordinated in order to allow efficient and skilled thought, in much the same way the cerebellum apparently contributes to the control of skilled action.

One relatively specific variant of this hypothesis is that the cerebellum is important for orienting attention (for reviews, see Courchesne and Allen, 1997; Akshoomoff, Courchesne, and Townsend, 1997). Attentional functions have been attributed to numerous brain structures (see Posner and Petersen, 1990), and considerable effort has been devoted to identifying the specific contributions of these structures. According to Courchesne

and colleagues, the cerebellar contribution to attentional functions is to rapidly prime task-relevant systems in order to enhance neural responsiveness. This anticipatory effect is assumed to be multimodal. Indeed, the fact that cerebellar neurons are responsive to auditory, visual, somatosensory, and perhaps even affective input, provides one of the main sources of motivation for this theory. The cerebellum is not necessarily the locus of the attentional commands. Rather, the cerebellum ensures that attentional commands are implemented in a rapid and coordinated manner. Thus, cerebellar lesions are not expected to produce dramatic attentional deficits such as neglect, but only to make shifts of attention slower and more effortful.

Evidence in support of the attention hypothesis comes from behavioral, electrophysiological, and neuroimaging studies (Akshoomoff, Courchesne, and Townsend, 1997). A series of studies have compared various patient groups on two monitoring tasks—a control task in which attention remains focused on a single dimension and an experimental task in which attention must be rapidly shifted between two dimensions. In both tasks, subjects are presented with a series of auditory and visual stimuli. On each dimension, one value is designated the target (e.g., red and high pitch) and one value is designated the distractor (e.g., green and low pitch). On the focused-attention task, subjects are instructed to respond to every target on a designated dimension, either color or pitch. On the divided-attention task, subjects alternate between the two dimensions, first responding to the color target, then the pitch target, then the color target, etc. (see figure 69.2).

Compared to control subjects, patients with cerebellar lesions, either associated with autism (Akshoomoff and Courchesne, 1992) or due to acquired cerebellar pathology (Courchesne et al., 1994), show a selective impairment on the divided-attention condition. For both groups, the deficit is evident only when the interval between successive targets is relatively short (e.g., less than 2.5 s). This is consistent with the idea that the cerebellum does not provide the attentional instructions, but rather ensures that such instructions are implemented rapidly (see also Townsend, Harris, and Courchesne, 1996). Importantly, the patients' performance is similar to controls on the focused-attention task regardless of whether the targets occur in rapid succession or are widely spaced in time. This dissociation would suggest that the problem is not motoric since the movement requirements are identical in the two tasks. Evoked potentials to the missed targets are comparable to ignored distractors, confirming that in such situations, the participants have failed to shift attention at the time of target presentation (Akshoomoff and Courchesne, 1994).

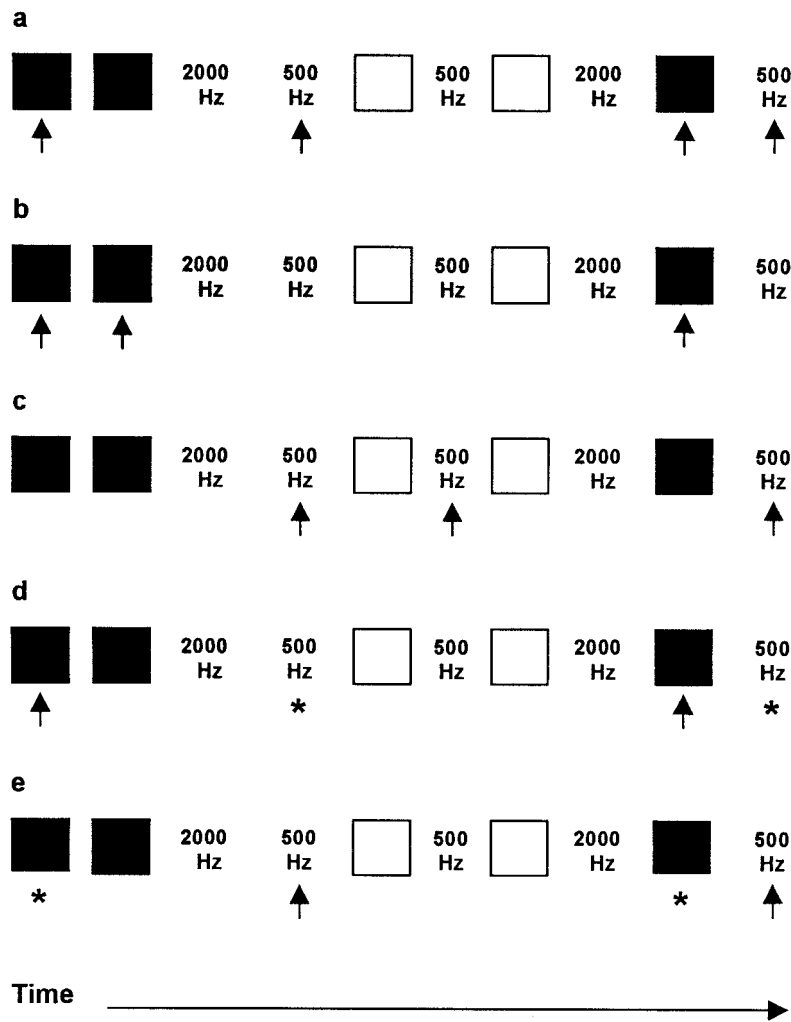

FIGURE 69.2 Attention tasks developed by Courchesne and colleagues to examine the cerebellar role in shifting attention. A stream of tones and colored patches is presented. In the divided-attention condition (a), subjects alternately responded to targets on the two dimensions and the inter-target interval was varied. In the focused-attention conditions, subjects responded only to the visual targets (b) or to the au-

ditary targets (c). In the Go/No-go version of the tasks, subjects alternated between the two dimensions, but responded only to targets on the visual (d) or the auditory (e) dimension. Patients with cerebellar lesions show a significant improvement in the Go/No-go version, despite the fact that the attention-switching demands are similar to those of the divided-attention condition.

While the attention hypothesis is intriguing, three other laboratories have failed to find a deficit in the performance of cerebellar patients on a visual selective-attention task that requires rapid orienting between spatial positions (Dimitrov et al., 1996; Helmuth, Ivry, and Shimizu, 1997; Yamaguchi, Tsuchiya, and Kobayashi, 1998). One possible account of this discrepancy is based on the idea that the deficits observed on the divided-attention task in the studies of Courchesne's lab reflect a more generic resource problem, one that is indirectly related to the motor problems of the cerebellar patients. The divided-attention task is considerably more difficult than the focused-attention task. In fact, many of the participants, both patients and controls, are near ceiling in the latter condition. Perhaps the patients have to devote

more processing resources to monitoring their key presses, a problem that causes them to miss rapidly appearing targets in the divided-attention condition. Motor control is certainly effortful for patients with cerebellar lesions, both in initiating and in terminating a movement.

Ravizza and Ivry (1998) have recently tested this hypothesis with a simple variant of the divided-attention task. In this version, subjects were again instructed to switch back and forth between the two dimensions following the detection of a target. However, they were to make overt responses to the targets on just one of the two dimensions. Targets on the other dimension simply required a covert shift of attention. With this design, the number of attentional shifts was equated in the two-response and one-response versions

of the divided-attention task. However, the rapid shifts in the latter condition never came on the heels of an overt response, ensuring that resources would not be diverted due to the production and termination of a preceding response. Ravizza and Ivry replicated the cerebellar deficit on the divided-attention condition when responses were required to targets on both dimensions. However, when overt responses were required on just one dimension, the patients with cerebellar lesions showed a large improvement, reaching performance levels comparable to those of control subjects. Thus, these results cast doubt on the hypothesis that cerebellar lesions disrupt attentional orienting, and suggest that the patients' deficits may be indirectly related to problems in motor control.

A sensory variant of the coordination and attention theoretical framework comes from the work of Bower and associates (see Bower, 1997), who have recently promoted the hypothesis that the emphasis on the cerebellum as a motor structure is somewhat misguided. Rather, they argue that the fundamental characterization of the cerebellum should focus on its role in sensory exploration. The intimate links of the cerebellum with motor systems reflect the fact that animals, especially humans, use somatosensory information as a way to gain knowledge about the environment and manipulate objects.

This theory does not posit a necessary role for the cerebellum in primary sensory or cognitive functions. Rather, the cerebellum is viewed as a support system, facilitating the efficiency with which sensory systems (especially the somatosensory system) acquire information. Gao and colleagues (1996) tested this hypothesis in a recent fMRI study. Activity in the dentate nucleus was monitored while subjects performed a series of tasks involving both active and passive manual exploration. In one experiment, subjects were asked to successively manipulate a series of unseen objects. In one condition, they simply picked up the objects, then placed them down. In the other condition, they had to pick up the objects, then judge if they matched a target object. Dentate activation was considerably greater in the discrimination condition. Similarly, the dentate was more active when various textured surfaces were passively moved across the subjects' stationary fingers if the subjects were required to evaluate the textures.

The sensory exploration idea is intriguing. While it has currently been applied to the somatosensory domain, Bower (1997) suggests the hypothesis may be more general. In one sense, this hypothesis is similar to the attention-shifting hypothesis outlined above. However, the cerebellum need not be viewed as essential for directing the focus of attention, nor for implementing

these shifts in a coordinated fashion. Rather, the focus of attention may be guided by noncerebellar structures, while the cerebellum contributes by ensuring that the selected information is processed with maximal efficiency to satisfy current task demands (see also Courchesne and Allen, 1997). A current weakness with this hypothesis is that, at present, there are minimal supportive data from patient studies. Somatosensory and proprioceptive functions are not generally assumed to be disturbed in patients with cerebellar lesions, although the examination of these functions has been rather crude.

ERROR DETECTION AND LEARNING A different focus of the role of the cerebellum in cognition is based on the idea that this structure operates as an important source of feedback, monitoring movement and thought in order to modify ongoing behavior, then using this information to alter future performance. This theoretical perspective draws upon the motor learning literature to explain cerebellar involvement in learning certain types of cognitive tasks, particularly those that improve with practice. These tasks include the verb-generation task described above, puzzle tasks in which the goal is to solve a puzzle in as few moves as possible while observing constraints on how the pieces can be positioned (e.g., the Tower of Hanoi), and motor sequence and trajectory learning tasks. Across these and related tasks, neuroimaging studies have demonstrated that cerebellar activity is high during initial performance of the task, that activity decreases as performance becomes more skilled and accurate, and that shifts in cortical activity co-occur with changes in cerebellar activity (e.g., Raichle et al., 1994).

Many of the cognitive tasks associated with cerebellar activation and practice-dependent changes are quite complicated, and thus the cerebellar activation can be interpreted in many ways. The cerebellar changes could reflect a correlation with learning, rather than a causal involvement. Some support for a causal relationship comes from converging neuropsychological studies. For each of the general tasks described above, impaired acquisition of skilled performance has been demonstrated in subjects with cerebellar damage or atrophy, though not all of the findings have been replicated.

The idea that the cerebellum is involved in the detection and correction of errors offers a potential causal link between on-line performance and learning. At the center of this idea in the motor domain is evidence that the cerebellum modifies output in the face of unexpected perturbations or sensory input. For instance, it has been hypothesized that during locomotion, corticocerebellar signals provide an efference copy of corticospinal motor commands that can be compared with afferent informa-

tion provided by spinocerebellar circuits (Kawato and Gomi, 1992). When a mismatch is detected, descending output from the cerebellar nuclei allows for rapid, on-line adjustments in the motor patterns without requiring extensive cortical intervention. Moreover, the error signals generated when the movement is perturbed are then used to modify the production of similar movements in the future (Gilbert and Thach, 1977). Similar ideas form the basis of computational models of the cerebellum's role in simple associative learning tasks such as eyeblink conditioning (reviewed in Thompson, 1988). Unexpected aversive stimuli such as an airpuff are assumed to provide an error signal in the cerebellum, modifying the animal's behavior so that it will make an anticipatory blink in the future when presented with the same context.

The cognitive generalization of this hypothesis implicitly assumes that the cerebellum has evolved so that it can now provide a more generic error-correction role, modifying internal thought in addition to external movement. Canavan and his colleagues (Bracke-Tolkmitt et al., 1989; Canavan et al., 1994) reported severe deficits on a conditional learning task in which the subjects had to learn the correct mapping between colored shapes and arbitrary verbal labels. The subjects were given no explicit instructions; rather, learning was solely through trial and error, with the experimenter indicating whether a response was correct or not after each trial. Fiez and colleagues (1992) report a case study of a patient who suffered a large infarct in the posterior and inferior region of the right cerebellar hemisphere. On standardized neuropsychological assessment, this patient's performance clearly indicated superior overall cognitive function. Yet the patient's performance on relatively simple verbal discrimination tasks, again involving trial-and-error learning, was extremely poor. Moreover, on a variety of tasks, he failed to use explicit verbal feedback from the experimenter to modify his responses. The same patient also failed to learn and perform the verb-generation task normally. Specifically, he produced a large number of inappropriate, but semantically related responses (e.g., producing "old" as a synonym for "garbage").

The dissociation between this patient's overall intelligence and his performance on these seemingly simple tasks is quite striking. It is not clear, however, whether these results provide strong support for the error-correction hypothesis. Issues remain, at least in part, because no explicit models have been developed to explain how error-correction would be implemented in a cognitive task; thus it is hard to evaluate whether some of the patient's difficulties fit within an error-detection framework. For example, the patient performed poorly in judging

whether two words were synonyms and in identifying whether common words were nouns or verbs. Since we can assume that he was, or had been, familiar with these words in the past, these deficits may indicate a disruption of semantic knowledge rather than an inability to make use of current error signals (and, indeed, he was given no feedback on such tests). A second issue is that of reproducibility. Helmuth and associates (1997) failed to replicate these findings in a group study of patients with focal cerebellar lesions. On the trial-and-error verbal discrimination task, these patients showed comparable learning functions across blocks of trials as age-matched control subjects. Similarly, on a speeded semantic generation task, the patients, while slower than controls, showed similar improvements over successive blocks.

Related to the ideas of both error detection and attention is the notion that the cerebellum may best be characterized as a predictive device, a neural structure that is specialized to make anticipatory adjustments (e.g., Courchesne and Allen, 1997; Paulin, 1997). For instance, through experience, a particular sensory context or internal state could become associated with a particular motor response or adjustment of the internal state. Eventually, the occurrence of a specific context could trigger the occurrence of a specific external or internal response; this procedure could be applied iteratively in order to produce a temporal sequence of internal events or overt responses. Models such as these emphasize the dynamic properties of cerebellar function (Raymond, Lisberger, and Mauk, 1996). A consistent feature of cerebellar theories is the focus on this system as performing predictive functions—the ability to anticipate forthcoming information and ensure that actions correctly anticipate changes in the environment.

GENERALIZED TIMING FUNCTION A specific variant of the prediction idea is that the cerebellum operates as an internal timing system, providing the precise representation of temporal information across a range of tasks (Ivry and Keele, 1989; reviewed in Ivry, 1997). The timing hypothesis originates in an analysis of the motor control deficits observed in animals and patients with cerebellar lesions. Cerebellar symptoms such as intentional tremor and hypermetria can be interpreted as resulting from the disorganization of the temporal pattern between agonist and antagonist muscles during rapid movements (Hore, Wild, and Diener, 1991). When asked to produce periodic movements, patients with cerebellar lesions exhibit a large increase in variability, and this increase is associated with central control processes regulating the timing of central motor commands (Ivry and Keele, 1989; Ivry, Keele, and Diener, 1988; Franz, Ivry, and Helmuth, 1996).

The timing deficits for these patients extend beyond the motor domain, being manifest in a variety of perceptual tasks that require the precise representation of temporal information. This temporal processing deficit has been found on perceptual tasks across different sensory modalities including audition (Ivry and Keele, 1989; Mangels, Ivry, and Shimizu, 1998), vision (Ivry and Diener, 1991; Nawrot and Rizzo, 1995), and somatosensation (Grill et al., 1994). A recent speech perception study provides an especially compelling demonstration of the importance of the cerebellum in temporal processing (Ackermann et al., 1997). Patients with cerebellar dysarthria, a difficulty in speech articulation, were unable to discriminate speech sounds that differed solely in the duration of an intersyllabic silent period (figure 69.3), yet performed comparably to control subjects for sounds that had different spectral cues.

Again, one might suppose a generalization of function over the course of evolution: A form of representation that evolved as part of a limited task domain might become accessible for the performance of other tasks that can exploit this specialization (Rozin, 1976). Within the framework of the timing hypothesis, the cerebellum must be critical for tasks that require precise timing, whether or not they are motoric. This hypothesis also provides a parsimonious account of the task domain of the cerebellum in learning, namely, when the response requires the representation of the temporal relationships between different stimuli or stimuli and responses. In eyeblink conditioning, for example, the learned response is adaptive only when it occurs at the right point in time, that is, when the animal has extracted the precise timing between the conditioning and unconditioned stimuli (Ivry and Keele, 1989). Without the cerebellar cortex, the association may be formed, but it loses its adaptive value, as evidenced by the fact that the animal no longer blinks when the aversive stimulus is presented (Perrett, Ruiz, and Mauk, 1993; Anderson and Keifer, 1997).

The research in this area has focused on tasks that impose real-time processing demands, and the corresponding computational models here have focused on how metrical temporal information might be represented in the cerebellar cortex (e.g., Buonomano and Mauk, 1994; Fiala, Grossberg, and Bullock, 1996). The representation of the temporal information is a central component of much of our perceptual experience and a prerequisite for skilled behavior. Consider the frog by the river gathering up an evening meal of flies, or the basketball player looking to pass the ball to a teammate who is moving toward the basket. Anticipating the future position of a moving stimulus and coordinating the multi-limb gestures required to interact with that stimulus re-

FIGURE 69.3 Identification functions for two speech continua in control subjects and patients with bilateral cerebellar lesions. For the tick-dick continuum, the voice-onset time was varied in steps of 10 ms. This change in the timing between voicing and the release of the stop consonant produces both temporal and spectral changes. For the boten-boden continuum, a silent interval was inserted between the syllables, thus providing only a temporal cue. The patients showed poor discrimination performance in this condition. (Adapted from Ackermann et al., 1997)

quires extremely precise timing. The cerebellum appears to be an exquisite device for this form of dynamic processing, and its manifestation in both perception and action reflects the intimate links between these domains that are required for skilled behavior.

As currently articulated, the conceptualization of a cerebellar timing system is limited to the relatively narrow temporal range that might be relevant for the control of coordinated movement. Here again, the motivation is based on an evolutionary perspective. An internal timing system likely emerged from a system that had access to information that contained temporal regu-

larities. A candidate here would be the pattern generated by a locomoting organism (be it terrestrial, arial, or aquatic). While locomotion signals might be generated by relatively simple spinal mechanisms, a hierarchical control system might be essential for endowing flexibility as well as for producing corrections in response to unexpected perturbations (Arshavsky, Gelfand, and Orlovsky, 1983). Perhaps the cerebellar timing system took root in this manner and the temporal extent of the cerebellum is constrained by its links to locomotion cycles.

The timing hypothesis is a narrower, more specific statement of how the cerebellum might be viewed as a predictive device. It is possible that a cerebellar timing function is simply one manifestation of a more general predictive capability (Ivry and Keele, 1989; Courchesne and Allen, 1997; Bower, 1997). On the other hand, in many situations, animals need to anticipate future events that do not require precise detail of the temporal structure of the series of intervening events. For example, the temporal requirements for knowing when to move on to a new foraging patch or when a signal light will change to green are quite different from that needed to anticipate when to swing a tennis racquet in order to serve a tossed tennis ball. And in other situations such as anticipating the next move in a chess game, skilled performance requires a predictive capability, but one that has essentially no temporal requirements. It remains to be seen whether the cerebellum contributes to tasks that entail prediction in this more generic sense. The timing hypothesis predicts that the cerebellum will not play a role in such tasks since its domain is assumed to be limited to tasks requiring a particular form of computation, the representation of the temporal relations between events.

IMAGERY, COVERT ACTION, AND WORKING MEMORY As reviewed above, the neuropsychological record is mixed regarding some of the more cognitive interpretations of cerebellar function. Nonetheless, there remains the challenge of interpreting the consistent finding of cerebellar activation in imaging studies, even when motor demands are equated in the experimental and control tasks. One hypothesis is based on the observation that there is a correlation between task difficulty and the degree of cerebellar activation (Ivry, 1997). Across a wide range of studies, metabolic activity in the cerebellum is most pronounced for the more difficult condition when pairs of tasks are compared.

It is, of course, necessary to operationalize "difficulty." One metric is based simply on the number of possible responses afforded by a situation: Tasks associated with a large number of possible responses are more difficult than those associated with a small number of possible responses. For example, in the language study of Pe-

tersen and colleagues (1989), there are more possible responses in the generate condition in which subjects must generate a semantic associate to the stimulus word compared to the control condition in which the subjects simply have to repeat the stimulus word. Similarly, in the difficult problem-solving condition of another study (Gao et al., 1996), there were four possible moves on each trial compared to just one in the easy condition. Perhaps the cerebellum is involved in the preparation and planning of candidate responses. The increased cerebellar activation in "difficult" conditions might reflect the parallel preparation of all the possible responses. By engaging in response preparation prior to completion of response selection, the system is able to respond in a more rapid manner. This hypothesis is in accord with the documented deficits in reaction time associated with cerebellar lesions (Meyer-Lohmann, Hore, and Brooks, 1977; Spidalieri, Busby, and Lamarre, 1983).

While this response preparation hypothesis can account for many of the imaging results, there are some notable exceptions. In a stem completion task (e.g., say "cougar" after seeing the stem "cou___"), cerebellar activation was found to be greater when there were few possible completions for the target stem than when there were many (Desmond, Gabrieli, and Glover, 1998). This result is the opposite of what one would predict based on the response preparation hypothesis. Another intriguing exception comes from a study comparing phonological and visual judgments of letters (Sergent et al., 1992). On each trial, a single letter was presented in the center of the screen, oriented either normally or mirror-reversed. In one condition, subjects judged the orientation, pressing one button if the stimulus was in its normal orientation and another if the stimulus was mirror-reversed. In a second condition, the same stimuli were presented, but now the judgment was based on whether or not the stimulus contained a target phoneme, the sound "ee" (as in B, D, or T). The tasks appeared to be of equal difficulty, both by the response alternative metric described above (two per trial) and by the fact that reaction times were comparable, with the phonological task taking slightly more time. Nonetheless, cerebellar activation was more pronounced in the orientation task.

An alternative view of the response preparation hypothesis is that response preparation and related action-related processes are essential to the critical cognitive operations required for these tasks. For instance, it is likely that imagery, in the form of mental rotation, is required for performing letter orientation judgments. A number of other neuroimaging studies have implicated the cerebellum in imagery tasks, especially when the task requires imagining motoric gestures. Compared to baseline

conditions involving rest, cerebellar activation is found when people imagine hitting a tennis ball (Decety et al., 1990) and when people perform either active or imagined hand gestures (Peter Fox, personal communication). Parsons and Fox (1998) report that cerebellar activation can occur even when subjects are not instructed to imagine movements. In their task, subjects were required to discriminate between line drawings of left and right hands shown from different perspectives. Based upon data from behavioral studies, it appears that subjects make these judgments by imagining they are moving their own hands to match the orientation of the stimulus hand.

Many verbal tasks may engage an articulatory form of imagery. For example, a key component of Baddeley's (1992) influential model of working memory entails a process by which linguistic information is actively maintained over short delays via covert (silent) articulatory rehearsal. The imaging literature suggests that the cerebellum may be an essential component of this rehearsal system. For example, increased blood flow is observed in the cerebellum when subjects are required to maintain five words over a 40-s delay interval (Fiez et al., 1996), or when they must decide whether each letter in a sequence is the same as the letter presented two trials previously, the so-called "two-back" task (Awh et al., 1996). It is important to note that task-related activation here, and in all of the imagery studies cited above, is not limited to the cerebellum. Meta-analyses indicate that the cerebellum, supplementary motor area (SMA), and Broca's area are active during verbal, but not spatial, working memory tasks, whereas regions such as dorsolateral prefrontal cortex are active during both verbal and spatial working memory tasks (figure 69.4; see also Fiez et al., 1996). This selective activation has led to the hypothesis that SMA, Broca's area, and the cerebellum comprise the neural basis of an articulatory rehearsal system (Awh et al., 1996; Fiez et al., 1996; Paulesu, Frith, and Frackowiak, 1993).

In evaluating the cerebellar contributions to imagery, one issue is whether its contributions to imagined movement are identical to its contributions to real movement. In terms of articulatory rehearsal, for instance, it may contribute to motoric aspects of internal speech representation in much the same way that it contributes to overt speech production. This hypothesis is consistent with behavioral evidence showing links between overt and covert articulation; for example, the number of items that subjects can maintain in working memory is correlated with the amount of time it takes to say them aloud (Baddeley, Thomson, and Buchanan, 1975). However, the observation of load-effects on cerebellar activation argues against overly simplistic interpretations of

FIGURE 69.4 The loci of peak activation associated with verbal working memory tasks (open circles) and spatial working memory tasks (filled squares) are plotted from a number of different PET studies. Broca's area in the left hemisphere, supplementary motor cortex in the superior medial cortex, and the medial and right lateral cerebellum are typically activated in verbal working memory but not spatial working memory tasks. Other areas, such as the right dorsolateral prefrontal cortex and the right inferior parietal cortex are activated by both verbal working memory and spatial working memory tasks. Verbal working memory coordinates drawn from (1) Awh et al., 1996; (2) Fiez et al., 1996; (3) Jonides et al., 1998; (4) Paulesu et al., 1993; (5) Petrides et al., 1993; (6) Salmon et al., 1996; (7) Schumacher et al., 1996; (8) Smith, Jonides, and Koeppel, 1996. Spatial working memory coordinates drawn from (1) Courtney et al., 1996; (2) Goldberg et al., 1996; (3) Owen et al., 1996; (4) Smith, Jonides, and Koeppel, 1996.

the relationship between real and imagined movement. As a control condition in studies of verbal working memory, subjects have been asked to internally rehearse relatively simple material that does not impose a memory load (e.g., count from 1 to 5 repeatedly or silently repeat a single letter). Cerebellar activation is greater in the experimental working memory condition than in these rehearsal conditions (Fiez et al., 1996; Desmond et al., 1997; Awh et al., 1996). Furthermore, cerebellar activation has been found to be higher in direct comparisons of high- versus low-load conditions (Desmond et al., 1997). While some of the changes in cerebellar activation reflect increases in areas active during both simple rehearsal and working memory tasks, others reflect the recruitment of areas that are not significantly active during simple rehearsal.

Viewing cerebellar contributions to verbal working memory from a more motoric perspective need not reduce its cognitive importance. A breakdown in the articulatory rehearsal system could have widespread consequences. Consider, for example, that verbal working memory is central to our ability to perform tasks that range from solving mathematical equations to comprehending sentence clauses. Furthermore, articulatory rehearsal and recoding have been associated with many other language tasks outside the domain of verbal working memory, such as speech recognition and the generation of word phonology. This may explain cerebellar activation in verbal fluency, stem completion, and verb generation tasks. Successful production of correct responses for these tasks may involve the ability to retrieve and maintain potential responses using a covert articulatory process (Desmond, Gabrieli, and Glover, 1998). There is also limited but provocative evidence implicating cerebellar dysfunction in developmental dyslexia (Fawcett, Nicolson, and Dean, 1996). Perhaps an inability to engage in fluent covert articulation interferes with the development of salient phonological representations. Without such codes, children are likely to have severe problems in acquiring reading skills (Liberman and Shankweiler, 1991).

Conclusions

As reviewed in this chapter, the cerebellum has stepped out from the shadows of its traditional role as part of the motor system, essential for the control of fine movement and balance. Patient, imaging, and modeling studies have brought the study of cerebellar function into the mainstream of cognitive neuroscience, with researchers hypothesizing links to attention, learning, memory, language, and thought. We have reviewed a diverse set of literatures here, seeking to identify the principal sources

of motivation for this mini-revolution and outlining some of the recent theoretical conjectures.

In general, we have adopted a somewhat skeptical perspective, seeking convergence from anatomical, neuropsychological, and neuroimaging studies for the proper evaluation of the various functional hypotheses that have been developed over the past decade. We do not intend this skepticism to be taken as an attempt to dismiss these hypotheses. It is essential to maintain an open mind as researchers develop experiments that will allow strong inference and seek theoretical accounts that may integrate various hypotheses. At the same time, the conservative nature of evolutionary processes leads us to expect that there will be some continuity between the contributions of the cerebellum to motor control and the contribution of this structure to language and thought.

ACKNOWLEDGMENTS This work was supported by Grants NS-30256 and NS-17778 from the National Institute of Health and IRI-9720350 from the National Science Foundation. The authors are grateful to Eliot Hazeltine, Steve Keele, Susan Ravizza, and Steven Kosslyn for their comments and to Kristi Hiatt for her help in preparing this chapter.

70 The Cognitive Neuroscience of Categorization

EDWARD E. SMITH AND JOHN JONIDES

ABSTRACT Behavioral work on categorization has proposed three different categorization procedures—classification by rule, by stored exemplars, and by prototype—and has often assumed that just one of these procedures underlies all acts of categorization. In this chapter, we use findings from cognitive neuroscience to argue that all three procedures are used in categorization and, further, that the three procedures have different neural bases. We discuss evidence from two kinds of studies. The first kind involves neuropsychological experiments with amnesic patients, and deals with the contrast between exemplars and prototypes. These studies indicate that amnesic patients can use implicit representations—presumably prototypes—in categorization tasks in which normal subjects use explicit exemplars. The second kind of study involves neuroimaging normal subjects while they perform categorization tasks that encourage the use of either rules or exemplars. These experiments indicate that rule use involves at least some neural circuits that are distinct from those involved in categorization by exemplars.

CATEGORIZATION PROCEDURES We routinely+ divide the world into categories—a particular wooden configuration is perceived as a *chair*, a particular assemblage of body parts as a *dog*, and so on. Categorization greatly reduces the amount of information we have to process, and allows us to draw inferences about imperceptible properties (e.g., “If it’s a dog, it may bark when provoked”). Categorization may be what makes possible human perception, memory, communication, and thought as we know it.

To categorize some test object “x” is to come to treat it as an instance of some category (a nonarbitrary class of objects). How do people do this? Presumably, we have some mental representations of various categories and procedures for deciding which of these mental representations provides the best fit for object x (Smith, 1995). In this chapter, we focus on categorization procedures themselves (as opposed to mental representations of categories). In particular, we consider three categorization procedures that have been widely studied in cognitive science, in order to see what recent findings in cognitive neuroscience can tell us about these procedures.

The three categorization procedures of interest can be roughly characterized in the following way (after Smith, Patalano, and Jonides, 1998). In deciding whether a test object belongs to a particular category, one may

1. determine whether the test object fits a rule that defines the category (“rule application”);
2. determine the similarity of the test object to one or more remembered exemplars of the category (“exemplar similarity”); or
3. determine the similarity of the test object to a prototype of the category (“prototype similarity”).

One issue arising from the extensive study of these procedures is central: Do people use a variety of categorization procedures? Or is all (or most) human categorization based on a single procedure? In its currently popular form the latter possibility involves the following reasoning: Categorization is always based on exemplar similarity; hence, what appear to be cases of rule application and prototype similarity can be shown, under more intensive analyses, to involve an exemplar-similarity procedure (Estes, 1994; Nosofsky, 1992a,b). We refer to this approach as the “unitary view.” The obvious alternative is the “multiple view”—that all three procedures are widely used in categorization. Among those who argue for multiple procedures, the major issues concern the nature of these mechanisms: What component processes are involved and how do they differ for the different procedures?

CONSTRAINTS FROM COGNITIVE NEUROSCIENCE Purely behavioral studies may be limited in what they can tell us about the question of unitary versus multiple categorization mechanisms. Most behavioral experiments on this issue have produced results that fit better with exemplar- rather than prototype-based mathematical models; however, this may be because exemplar models contain more information (they contain representations of *all* relevant exemplars, whereas prototype models discard much of this information). Also, while quantitative modeling favors exemplar models, some qualitative considerations favor prototype models (e.g.,

EDWARD E. SMITH and JOHN JONIDES Department of Psychology, University of Michigan, Ann Arbor, Mich.

Smith, 1995). Thus, there is a clear need to consider another kind of evidence about categorization; for this reason, we turn to more neurologically based research.

Findings from cognitive neuroscience can contribute both to the general issue of unitary versus multiple categorization procedures and to specific issues about component processes. In this chapter, we consider two cases of such contributions from cognitive neuroscience. In the first section, we focus on exemplar-similarity and prototype-similarity procedures, and we consider evidence from amnesic patients in categorization tasks. Such patients should have serious difficulty in learning exemplars of new categories, and consequently their performance in categorization tasks can be revealing about an exemplar mechanism. If categorization is based solely on similarity to remembered exemplars, then amnesics' performance should be very poor compared to that of normals; but if categorization can be accomplished by other means, amnesics' performance might be normal in some cases.

In the second section, we focus on the contrast between exemplar similarity and rule application. Again, we consider some evidence from neuropsychology, noting how different kinds of patients perform in different kinds of tasks. Here, however, we concentrate on neuroimaging studies that attempt to show that different neural processes are involved when people categorize the same objects by different procedures.

Throughout, the studies that we review involve artificial categories (e.g., categories of dot patterns or imaginary animals) rather than natural categories (e.g., dogs or hammers). We emphasize artificial categories because of our concern with categorization procedures: Artificial categories maximize the chances that the categorization procedure of interest is employed. In seeking to determine if rule application is ever employed, one will do better to create, for example, a set of imaginary animals conforming to a novel rule instead of trusting that some particular natural category is, in fact, based on a rule.

Exemplars, prototypes, and categorization by amnesic patients

LOGIC OF THE RESEARCH It is useful to begin by fleshing out the two procedures of interest. To illustrate paradigmatic cases of exemplar- and prototype-similarity procedures, consider a situation in which a dermatologist must decide whether a particular skin lesion is an instance of disease Y.

Assuming the dermatologist has seen many patients, she will likely have stored in long-term memory numerous exemplars of various skin diseases. She may then note that the current lesion is very similar to stored ex-

emplars of disease Y, and on this basis categorize the current lesion as an instance of Y. The sequence of processes presumably includes

1. retrieval of stored exemplars (of various disease categories) that are similar to the current lesion (the test object); and
2. selection of that category whose retrieved exemplars are (by some measure) most similar to the test object.

Note that if the exemplars retrieved in stage 1 all belong to the same category, then the selection process of stage 2 is trivial (or nonexistent). But if the exemplars retrieved in stage 1 belong to different categories, then stage 2 requires a systematic choice process (see, e.g., Estes, 1994; Nosofsky, 1992a,b).

Categorization based on prototype similarity is somewhat different. We assume that, as a consequence of seeing numerous patients, our dermatologist has abstracted from the individual cases a prototype of each relevant skin disease. This prototype is some measure of central tendency of lesions within a disease category—perhaps an average over the dimensions of shape, texture, and color, or the modal values on these dimensions. In any event, our dermatologist might note that the current lesion is more similar to the prototype of disease Y than it is to rival prototypes, and on this basis categorize the current lesion as an instance of Y. The sequence of processes presumably includes

1. retrieval of prototypes (of various disease categories) that are similar to the current lesion; and
2. selection of that category whose prototype is most similar to the test object.

In behavioral research we find numerous studies that directly contrast exemplar similarity and prototype similarity in specific categorization tasks (see Estes, 1994, for a partial review). Typically, the tasks require normal subjects to learn and subsequently use some artificial categories—say, two categories of dot patterns, or schematic faces. The researchers develop quantitative models of exemplar-similarity and prototype-similarity procedures, then determine which model provides a better fit to the data on category learning and use. As previously noted, many of these studies have favored exemplar-similarity models, so much so as to suggest that categorization with novel categories is always done by exemplar similarity (this is the unitary view). Importantly, these studies have frequently bolstered their case for exemplar-based categorization by showing that the representations assumed for categorization can also be invoked to explain performance on tests of recognition memory. That is, an experiment may require subjects to learn the

instances of two novel categories of visual patterns, then test the subjects both on categorization with novel items and on recognition of the originally learned instances. One can then use modeling techniques to show that the same representations are involved both in categorization and long-term recognition memory (e.g., Nosofsky and Zaki, 1998; Shin and Nosofsky, 1992).

The link between categorization and recognition memory indicates that the memory representations involved are *explicit*. That is, the representations contain information about the context in which the item occurred, and may also permit conscious recollection of the item. These characteristics of explicit representations provide a basis for responding in tasks like recall and recognition. All of this is in contrast to *implicit* representations, which can provide a basis for performance changes but cannot be intentionally reinstated (see, e.g., Bower, 1998; Schacter, 1989).

This is where neuropsychology enters the picture. One of the best documented sets of findings in the field involves amnesic patients: Amnesics with damage either to medial-temporal-lobe or diencephalic structures have difficulty committing new information to explicit memory (see Squire, 1992, for a review). Amnesics should therefore have difficulty employing the exemplar-similarity procedure in learning and using novel categories, since the exemplars involved are presumably part of explicit memory. Under the unitary view that all categorization is based on exemplar similarity, amnesics should perform poorly in *all* tasks that require the learning and use of novel categories. Under the multiple-procedures view, however, amnesics should perform poorly in those categorization tasks that elicit an exemplar-similarity procedure, but they may perform normally on tasks that recruit other procedures, as long as these other procedures place a minimal load on explicit memory. Prototype similarity might be such an “other” procedure. These ideas were tested in the studies described in the following section.

AMNESIC PERFORMANCE IN CATEGORIZATION TASKS

Using the above logic, Kolodny (1994) compared normal controls and a group of medial-temporal-lobe and Korsakoff’s amnesics on two different categorization tasks. One task involved paintings and presumably elicited an exemplar-similarity procedure, whereas the other task involved dot patterns and presumably triggered prototype similarity.

Consider first the dot-pattern task. In a *learning phase*, subjects were presented a sequence of dot patterns and were informed in which of three categories each pattern belonged. Every pattern, which contained nine dots, was generated by statistically distorting one of three proto-

type patterns. In a subsequent *test phase*, the subjects were presented the learned patterns plus novel ones, then asked to indicate the appropriate category for each one. This kind of task has been widely used in categorization studies with normal subjects, and performance on the task has typically been interpreted in terms of prototype similarity (e.g., Posner and Keele, 1968; Homa, Sterling, and Trepel, 1981). Following the categorization task, subjects were shown patterns they had categorized as well as completely novel ones, then were asked to decide which ones were “old” and which “new”; this is a recognition test of explicit memory.

The paintings task was similar in structure: a learning phase, followed by a test phase that involved learned and novel items, followed by a recognition task. But now the items were Renaissance paintings, and categorization required the subjects to learn which paintings were done by the same artist. Prior research indicated that categorization in this task was based on exemplar similarity; indeed, paintings done by the same painter were sufficiently dissimilar that it is difficult even to generate a plausible prototype for each artist (Hartley and Homa, 1981).

The results for the paintings task were exactly what one would expect if categorization were mediated by exemplar similarity. Amnesics performed far worse than normal controls during both the training and test phases of categorization. Indeed, amnesic categorization performance did not differ significantly from chance. As corroborating evidence that the control/amnesic difference in categorization was mediated by an underlying difference in retrieval from explicit long-term memory, amnesics performed more poorly than normals on the recognition memory test. There is, then, a clear connection between explicit memory and categorization of novel items, just as has been found in the studies with normals, and all of this is in keeping with an exemplar-similarity procedure.

The results are very different for the task involving dot patterns. Here, amnesics performed as well as normal controls during both the training and test phases of categorization. This suggests that categorization was based on a mechanism other than exemplar similarity. This suggestion is strengthened by the results on the recognition memory test, on which amnesics performed more poorly than normals. In the dot-pattern task, then, there is a dissociation between memory and categorization, with amnesics being impaired on the former but normal on the latter. The magnitude of this dissociation is striking, as amnesic patients achieved their normal categorization while performing at chance on the memory test. It therefore seems highly likely that a mechanism other than explicit exemplar similarity was involved in the categorization of dot patterns.¹

A report by Squire and Knowlton (1995) contains even more dramatic evidence for a dissociation between categorization and explicit memory (see also Knowlton and Squire, 1993). These researchers worked with a severely amnesic patient E.P. who, according to standard tests, has virtually no capacity for explicit memory (unlike the patients in the preceding study, who scored above chance on recognition memory for paintings). But despite his complete loss of memory, E.P. is normal on the categorization of dot patterns. In one study, E.P. and a group of normal controls were presented a series of dot patterns during a training phase; all patterns were distortions of the same prototype. In a test phase, E.P. and the controls were presented novel patterns, which included the prototype itself, distortions relatively similar to the prototype ("low distortions"), distortions relatively dissimilar to the prototype ("high distortions"), and random dot patterns. The subjects' task was to decide which of these test patterns belonged to the same category as that exemplified in the training phase. As in prior studies with normal subjects, the controls gave their highest ratings ("Yes, it's a member of the category") to the prototype, next highest to the low distortions, and next to the high distortions, giving their lowest rating to the random patterns. E.P. did the same, and to the same degree. There were no significant differences between E.P.'s gradient of categorization and that of the normals.

This is only half the dissociation between categorization and memory. E.P. and the normal controls were also given an extremely simple recognition-memory test. A single dot pattern was presented 40 times in succession, and 5 minutes later subjects were given a recognition test in which they had to decide whether each pattern presented was the memory pattern or not. Unsurprisingly, control subjects were almost perfect on this test. But E.P. performed at chance. Thus E.P. completely failed the simplest test of explicit memory, but was perfectly normal on a categorization test with the same kind of stimuli. Clearly, E.P.'s categorization performance cannot be based on explicit memory, hence not on an (explicit) exemplar-similarity procedure. There must be some other procedure in use.

PROTOTYPES AND EXPLICIT VERSUS IMPLICIT MEMORY On the face of it, that other procedure would likely be prototype similarity. For one thing, prior work suggests that the categorization of dot patterns is accomplished by a prototype-similarity mechanism (e.g., Posner and Keele, 1968; Homa, Sterling, and Trepel, 1981; but see Shin and Nosofsky, 1992). Another point is that prototype similarity makes minimal demands on long-term explicit memory. Because the dot patterns are pre-

sented every few seconds during the training phase, subjects can extract a prototype simply by holding in working memory (which is spared in amnesia) the measure of central tendency they have extracted thus far, combining it with the next item to form a new prototype. But there is a problem with the claim that prototype similarity is the mechanism operative in the dot-pattern categorization tasks of the preceding studies. Subjects would have to store the prototype in long-term memory between the training and test phases (usually, a matter of minutes), as well as during the test phase (again, a matter of minutes). However, patient E.P., who cannot store a single item for minutes, performs normally on dot-pattern categorization.

There are a couple of possible solutions to this dilemma. One is that the categorization procedure that E.P. and other amnesic patients use is not prototype similarity, but some more primitive procedure that has been spared in amnesia. The only such primitive procedure in sight is a simple mechanism that forms associations between stimulus cues and categories in a manner analogous to classical conditioning. Amnesic subjects might, for example, learn to associate a set of dots in a certain region with category A. This kind of associative mechanism has been used to explain performance in probabilistic categorization tasks, tasks in which the features of objects are only probabilistically related to categorization. In such tasks, amnesics again sometimes perform as well as normals (e.g., Knowlton, Squire, and Gluck, 1994). However, it seems unlikely that the associative mechanism that underlies probabilistic categorization is involved in dot-pattern categorization, since there is a dissociation between the two tasks. Parkinson's patients are impaired in the probabilistic categorization task, yet perform normally on dot-pattern categorization. Hence, two different categorization mechanisms may be involved in the two tasks (Reber and Squire, 1997).²

So what procedure is used in dot-pattern categorization? Perhaps the abstraction and use of prototypes requires only implicit, not explicit, memory; consequently, amnesic patients may be able to use an implicit prototype for categorization purposes (which, of course, would not work for recognition). What would an implicit prototype contain? Likely, it would represent the central tendencies of the items presented (like an explicit prototype), but not associations with context (unlike an explicit prototype) (e.g., Bower, 1998). The establishment of such contextual associations is at least part of what distinguishes explicit from implicit representations, and this process requires an intact medial-temporal-diencephalic system.³

CONCLUSIONS What can we conclude about categorization procedures from this line of work? First, at least in

some tasks, categorization need not be based on explicit memory. Because exemplar similarity has been tied to explicit memory in experiments with normal subjects, it follows that categorization need not be based on exemplar similarity. In contrast, there *are* tasks in which categorization performance is tied to explicit memory (e.g., the paintings task used by Kolodny, 1994), and in such cases exemplar similarity seems the most plausible account of categorization. Thus, in contrast to the unitary view, there appears to be more than one mechanism of categorization, and at least one of these mechanisms is spared in amnesia. The best guess about the spared mechanism is that it is prototype similarity, with the prototypes involved being implicit representations. These conclusions are in rough agreement with conclusions drawn by Knowlton, Squire, and their co-workers.⁴

Exemplars, rules, and categorization by normal subjects

LOGIC OF THE RESEARCH We turn now to a second line of research on categorization procedures, one that focuses on the contrast between exemplar similarity and rule application, and involves the neuroimaging of normal subjects as well as the behavioral study of neurological patients. We have already characterized the exemplar-similarity procedure, and it is useful to do the same for rule application. Returning to our dermatologist, suppose she knows the additive rule: If the lesion has a sufficient number of the following features—elliptic shape, bumpy texture, reddish-brown coloring, etc.—then disease Y is indicated. If the dermatologist applies this rule in making her diagnosis (categorization), presumably she will engage in the following sequence of processes (after Smith, Patalano, and Jonides, 1998):

1. selectively attend to each critical attribute of the test object (e.g., the shape, texture, and color of the lesion);
2. for each attended-to attribute, determine whether the perceptual information instantiates the value specified in the rule (e.g., “Is this color reddish-brown?”); and
3. amalgamate the outcomes of stage 2 so as to determine the final categorization.

The first stage involves selective attention, the second involves the perceptual instantiation of abstract conditions, and the third requires the working-memory operations of storing and combining information.

Given this characterization of rule application and our previous one of exemplar similarity, we can now consider how data from cognitive neuroscience can be used to determine if the putative mechanisms are distinct, as well as the nature of their component processes. One approach is to look for dissociations between the pro-

cesses of interest in different patient populations; for example, brain damage in frontal regions may lead to a deficit in tasks requiring rule application, but not in tasks requiring exemplar similarity. We will briefly consider such neuropsychological evidence. A second approach is to use neuroimaging techniques to compare categorization based on rule application versus that based on exemplar similarity. This approach allows us to determine the neural regions activated in a particular categorization procedure, and then to use what is known about the functionality of the activated regions to infer the processes involved in the categorization procedure. We will review a PET study that embodies this approach.

NEUROLOGICAL PATIENT PERFORMANCE ON CATEGORIZATION TASKS What neural regions are involved in the application of rules? For years, the best guess has been frontal regions, particularly the dorsolateral prefrontal cortex (DLPFC). One source of suggestive evidence comes from clinical observations of patients with selective frontal lesions. Such patients seem to be particularly deficient in complex tasks, like planning and decision making, and some of this deficiency is thought to arise from the patients’ inability to follow explicit rules (e.g., Luria, 1969). A second line of evidence comes from experiments that demonstrate that frontal-lobe patients, particularly those with DLPFC damage, have difficulty in a categorization task that requires the use of explicit rules, the Wisconsin Card Sort task. In this task, on each trial a card is presented that contains geometric forms, the forms varying from card to card with respect to number, shape, size, and background shading. The subjects must first learn which of the four attributes to use as a basis for sorting the cards; and, once they have learned this, the experimenter switches the relevant attribute, so subjects must now discover the new critical attribute. The basic finding is that frontal-lobe patients are relatively normal in learning the initial rule, but are impaired in shifting to a new rule when the experimenter switches relevant attributes (e.g., Milner, 1964).

This finding has frequently been interpreted in terms of deficient use of rules, but a related explanation may be more plausible. The frontal-lobe patients’ major deficit may be in *switching* between rules rather than in *applying* them. Indeed, frontal-lobe patients may be deficient in switching their attention between *any* two mental processes. Support for this interpretation comes from studies showing that patients with DLPFC lesions are selectively impaired in switching between two simple tasks (e.g., sorting by color versus sorting by shape), even when compared to neurological patients who have lesions in other parts of frontal cortex (Rubenstein, Evans, and

Meyer, 1994). Further evidence that the DLPFC is involved in switching internal attention comes from neuroimaging studies with normal subjects. While having their brains scanned by functional magnetic resonance imaging (fMRI), subjects were required to perform categorization and mental-rotation tasks concurrently, or to perform each task alone. When doing both tasks concurrently, and hence switching back and forth between them, DLPFC was activated; when the tasks were performed alone, and hence no switching was required, there was no activation in DLPFC (D'Esposito et al., 1995). So it may be that the DLPFC is involved in rule-based categorization to the extent the task requires switching attention between mental processes. Such attention switching is bound to occur when the rule involves multiple attributes. For one thing, the categorizer must switch attention between attributes; for another, the categorizer must remember the outcomes of attributes already tested while interrogating the remaining attributes, and this too may require switching of attention.

If we assume that the DLPFC is involved in many cases of rule application while medial-temporal-lobe and diencephalic structures mediate exemplar similarity, the stage is set for a possible neuropsychological double dissociation between the two categorization procedures; for example, an experiment that tests DLPFC and medial-temporal-lobe patients in two categorization tasks—one that recruits primarily rule application and one that rests on exemplar similarity. To our knowledge, no such attempt at a double dissociation has been published.

A NEUROIMAGING CONTRAST BETWEEN RULE APPLICATION AND EXEMPLAR SIMILARITY To obtain stronger evidence for a distinction between rule application and exemplar similarity, we had normal subjects perform either a rule- or exemplar-based categorization task while having their brains imaged by positron emission tomography (PET). The categorization tasks (adapted from prior work by Allen and Brooks, 1991) required subjects to learn to sort pictures of artificial animals—exemplified in figure 70.1—into two categories. Two different groups of subjects were tested, one induced to categorize the animals by rule, the other induced to categorize the very same animals on the basis of remembered examples.

Both groups went through a training and a test phase. During training, subjects in the rule group learned to sort the ten animals into the two equal-sized categories by applying an explicit rule. The rule stated that an animal was from one of the categories if it had at least three of five critical features. For example: “An animal is from Venus if at least three of the following five are true: an-

FIGURE 70.1 Examples of artificial animals used in the PET studies of rule-based versus memory-based categorization.

tennae ears, curly tail, hoofed feet, beak, and long neck. Otherwise, it is from Saturn.” After training, rule subjects participated in a test phase while being scanned by PET. Only novel animals were presented, and subjects continued to categorize by the training rule. The memory group had comparable training and test phases. During training, subjects learned to sort the ten animals into the appropriate categories, relying totally on their memory for previous categorizations (feedback was given during training, so subjects could remember to which category each animal belonged). During the test phase, again subjects had to categorize novel animals while being scanned by PET. But memory subjects presumably based their decisions about the test animals on similar exemplars they learned during training (this is the conclusion supported by the behavioral findings of Allen and Brooks, 1991).

Before considering the PET data, it is useful to look at the behavioral data in the test phase, to provide corroborating evidence that the rule and memory groups were indeed using two different categorization procedures. Two kinds of test items were of particular importance: (1) a test animal that, according to the rule, was a member of one category, say Venus, and also was extremely

similar to a learned item known to be a member of Venus; and (2) a test animal that, according to the rule, was a member of one category, say Venus, but also was extremely similar to a learned item known to be a member of the other category, Saturn. Thus, for type 1 items, both rule application and exemplar similarity should yield the same categorization, whereas the two procedures should yield different decisions for type 2 items. Subjects showed exactly this pattern—rule and memory subjects agreed on the dominant categorization of type 1 items, but not on type 2 items. With regard to the latter, rule subjects categorized 71% of type 2 items according to the rule, whereas memory subjects categorized 76% of type 2 items in terms of similarity to learned exemplars (which goes against the rule). These behavioral data therefore show the expected dissociation between rule application and exemplar similarity. Do the imaging data show such a dissociation as well?

The PET data obtained during the test phase should reflect neural differences between rule application and exemplar similarity. To aid in interpreting the PET data for categorization, subjects in both the rule and memory groups also performed a control task while being scanned. In this control condition, subjects simply looked at each presented animal and arbitrarily made one of two responses. The results obtained during this control task were subtracted from those obtained during the categorization tasks to remove activations due to noncategorization processes (e.g., perceptual and response processes; see Posner et al., 1988).

The subtraction images revealed numerous areas of significant activation, all of which are presented schematically in figure 70.2. The cortical areas are labeled on the schematic using Brodmann numbers, whereas cerebellar regions are designated by Cb. The finding most evident in the schematic is that of a dissociation: Of the twenty-three areas activated across both conditions, fourteen were activated solely in the rule condition. Of the remaining nine areas, seven were active in both conditions, and only two were active in the memory condition alone.⁵

Among the areas distinct to the rule condition, some are of particular significance because of what is known about their functionality. These include two areas in bilateral superior parietal cortex (Brodmann area, or BA, 7), one area in right-hemisphere DLPFC (BA 46), and three areas in bilateral supplementary motor cortex (BA 6). The superior parietal region is known to be involved in selective attention to spatial positions. Thus, studies with human neurological patients show that damage to this parietal region is associated with impairments in spatial, selective attention (Posner and Dehaene, 1994). As we noted earlier, spatial selective attention should

have been involved in rule application, because subjects had to selectively attend to the location of each relevant attribute. The DLPFC activation also fits with rule use. Earlier, we reviewed evidence that this region is activated in a task that requires changing rules, and shifting between the different attributes might be comparable to shifting rules. Finally, the three premotor activations are routinely found in imaging studies of working memory (Smith and Jonides, 1997), and, as previously argued, categorization based on a multi-attribute rule requires the involvement of working memory. Thus, what is known about the functions of these rule-distinct areas fits well with prior conceptions of what is involved in rule application.

There were seven areas of activation common to both rule and memory groups. These include five areas in the visual cortex (one in left BA 17, one in left and one in right BA 18, one in left BA 18/37, and one in right BA 19) and two areas in the right cerebellum. We have no interpretation of the functions of the cerebellar areas, but there are a number of possibilities for the functions of the occipital activations. One possibility is that some automatic exemplar retrieval occurred even in the rule condition (because the test items were similar to the training animals), and the occipital activations reflect this retrieval of visual memories. A second possibility is that both categorization conditions required a fuller perceptual analysis of the test animals than did the control condition, and this additional analysis is the source of the occipital activations. And a third possibility is that, given that the occipital areas were only *roughly* in the same locations for the rule and memory conditions, they may be the result of different kinds of perceptual processing in each condition (e.g., perceptual testing of rule-relevant attributes in the rule condition versus retrieval of visual memories in the memory condition).

The two areas active only in the memory condition were in visual cortex (left BA 18) and the left cerebellum. Because these areas are in regions in which common rule and memory areas were also found, it seems unlikely that the two areas reflect novel cognitive processes. More likely, they may fit with one of the three possibilities discussed in the preceding paragraph.

In sum, the PET results show a dissociation between the neural regions activated in the rule and memory conditions, and the rule-distinct areas may mediate mechanisms unique to rule use, namely selective attention and working memory.

Concluding remarks

Our PET results indicate that different neural mechanisms underlie rule application and exemplar similarity.

FIGURE 70.2 The marked areas on the left and right lateral surfaces of the cortex denote regions of significant activation in the rule- and memory-condition subtraction images. Circles designate the rule condition, squares the memory condition; numbers designate Brodmann areas, and Cb designates cere-

bellum. The only active regions that are not visible from this perspective are left BA 32 (memory condition only) and right thalamus (rule condition only). (Adapted from Smith, Patalano, and Jonides, 1998.)

This distinction between procedures is also supported by the neuropsychological evidence that we reviewed, though that evidence is considerably less diagnostic than the PET findings. All things considered, the evidence from cognitive neuroscience supports the cognitive dis-

tinction between rule application and exemplar similarity as categorization mechanisms. Earlier, we showed comparable evidence for a distinction between exemplar similarity and prototype similarity. Putting this together, we have support for three different categorization proce-

dures, which argues against the unitary view of categorization and for the multiple-procedures view.

In addition, the various studies tell us something about the processes involved in the three categorization procedures. The poor performance of amnesic patients on a task that clearly requires exemplar retrieval (the paintings task) indicates that the heart of this procedure is retrieval from explicit, long-term memory. This proposal is consistent with the PET findings showing that most of the activation during memory-based categorization is in the posterior part of the brain, where visual memories are presumably stored. The good performance of amnesics on tasks that seem to require prototype similarity (dot-pattern categorization) indicates that, whatever the component processes involved in this procedure, the representations are implicit. And, finally, the PET findings obtained during rule-based categorization indicate that the processes involved in rule application include selective attention and working memory.

Finally, we note that while we have focused on procedures of categorization, much of the neural activation mediating any act of categorization is determined by the contents of the categories, i.e., by *what* is been categorized, not just *how* it is categorized. For example, in our PET study, we might have used verbal descriptions of the imaginary animals instead of pictures—and likely would have found less activation in occipital regions and more in language areas in both the rule and memory conditions. Similarly, neuroimaging studies of dot-pattern categorization show activation in occipital areas, areas that are known to be involved in the initial encoding of visual-spatial information (Reber, Stark, and Squire, 1998).

Content effects have also been obtained in neuroimaging studies of natural categories. In some experiments, subjects are first told the name of a target category (e.g., *vegetable*), and then decide whether named test objects (e.g., lettuce, apple) are instances of the target category. Activation is routinely observed in the left-hemisphere angular gyrus, known to be involved in the processing of linguistic information (e.g., Grossman, Robinson, and Jaggi, 1996). In other studies, the same kind of categorization task is used, but the test items are presented pictorially rather than verbally (e.g., Kosslyn, Alpert, and Thompson, 1995). Now activation is observed in occipital cortex, not in the angular gyrus. Thus, while the categorization procedure is presumably the same in these verbal and visual tasks—prototype or exemplar similarity (e.g., Smith, 1995)—the activation patterns vary in predictable fashion with the kind of information being categorized. A true understanding of the neural bases of categorization, then, must consider both the content of

the representations and the procedures that operate on them.

ACKNOWLEDGMENTS Preparation of this paper, and some of the research reported here, was supported by grants from the National Institute on Aging and the Office of Naval Research.

NOTES

1. A dissociation between performance in categorization and recognition memory tasks has often been taken as strong evidence that different processes are involved in the two tasks. But insightful analyses by Nosofsky and Zaki (1998) challenge the evidentiary status of such dissociations. Essentially, these authors demonstrate that such a dissociation could arise if: (1) categorization is based on exemplar similarity, and hence both tasks involve the same memory representations; (2) the categorization task requires a less demanding memory discrimination than does the memory task; and (3) the amnesics have diminished memory capacity (which they surely do). Kolodny's (1994) specific dissociation between dot-pattern categorization and memory might not survive Nosofsky and Zaki's critique. However, the study of amnesic patient E.P. (Squire and Knowlton, 1995; Knowlton and Squire, 1993) would survive this critique (as noted by Nosofsky and Zaki themselves), presumably because the recognition memory task involved was extremely easy.
2. Nosofsky and Zaki's (1998) distrust of dissociations (see note 1) applies here as well. However, the dissociation at issue—that between probabilistic categorization and dot-pattern categorization—is unlikely to hinge on the two tasks' having differential memory requirements. But the dissociation could arise if (1) categorization is based on prototype similarity in both tasks; (2) the extent to which test objects were more similar to one category prototype than the other was greater in the dot-pattern than the probabilistic-categorization task, and hence the decision was more difficult in the probabilistic-categorization task; and (3) Parkinson's patients are impaired in making similarity-based decisions, and hence performed less well in probabilistic categorization.
3. Since we have raised the specter of an implicit prototype, what about the possibility that amnesics rely on implicit exemplars when categorizing dot patterns? At least two reasons argue against the latter possibility. First, if categorization can be based on exemplars, why didn't the amnesic subjects in Kolodny's (1994) experiment use such exemplars to perform normally on the paintings task? This task almost certainly requires exemplar-based categorization, yet amnesic performance on it was at chance, suggesting that the exemplars involved had to be explicitly represented. Second, as noted earlier, there is some independent evidence that the categorization of dot patterns is done by a prototype (e.g., Homa, Sterling, and Trepel, 1981).
4. Ashby, Alfonso-Reese, and Turken (1998) have also proposed distinct neural systems for explicit and implicit categorization mechanisms, but they identify the explicit system only with rule application.
5. Each area of activation contains a peak—a point of greatest change in activation within the area—that can be specified in

an x,y,z -coordinate system. An area of activation found in the rule condition is considered "common" to an area found in the memory condition if the peaks of the two areas differ by less than 10 mm—the approximate spatial resolution of PET—on each coordinate.

Category Specificity and the Brain: The Sensory/Motor Model of Semantic Representations of Objects

ALEX MARTIN, LESLIE G. UNGERLEIDER, AND JAMES V. HAXBY

ABSTRACT The semantic representation of an object is composed of stored information about the features and attributes defining that object, including its typical form, color, motion, and the motor movements associated with its use. Evidence from functional brain imaging studies of normal individuals indicates that this information is represented in the brain as a distributed network of discrete cortical regions. Within this network the features that define an object are stored close to the primary sensory and motor areas that were active when information about that object was acquired. Thus, the organization of semantic information parallels the organization of the sensory and motor systems in the primate brain. This organizational scheme provides a basis for understanding category-specific disorders of knowledge resulting from focal brain damage based on the premise that the distinction between members of different categories of objects, such as animals and tools, is dependent on access to information about different types of features. Storage of information about such features as form, color, motion, and object use-associated motor movements in separate regions of the brain may provide innately determined, neurobiologically plausible mechanisms that function in the service of referential meaning.

One of the most puzzling and intriguing consequences of focal brain injury is a category-specific disorder of knowledge—a selective difficulty naming and retrieving information about objects from a single semantic category. Reports of such patients have appeared in the clinical literature for more than 100 years (for review see Nielsen, 1958), but it is mostly in the past 10 to 15 years that significant progress has been made in understanding these category-specific effects. This progress is due largely to the seminal work of Elizabeth Warrington and her colleagues in the mid-1980s (Warrington and McCarthy, 1983, 1987; Warrington and Shallice, 1984), the ever-increasing number of careful case studies and theoretical analyses that followed (e.g., Allport, 1985; Damasio, 1989, 1990; Farah and McClelland, 1991; Farah, Mc-

Mullen, and Meyer, 1991; Hillis and Caramazza, 1991; Humphreys and Riddoch, 1987; Saffran and Schwartz, 1994; Shallice, 1988), and, more recently, functional brain-imaging studies of normal individuals.

This chapter focuses on functional brain-imaging studies of semantic object processing and on category-specific effects using positron emission tomography (PET) and functional magnetic resonance imaging (fMRI). Although these studies are in their infancy, the available evidence suggests that the study of object recognition and object naming can provide us with a window into the much broader issue of how information is stored and organized in the cerebral cortex.

In 1988, Petersen, Posner, Raichle, and colleagues published the first report on the functional neuroanatomy of semantic processing in the normal human brain (Petersen et al., 1988). Using PET, they presented single words (concrete nouns; e.g., “cake”) and asked their subjects to generate a word denoting a use associated with the noun (e.g., “eat”). Comparison of activity recorded during this scan with activity recorded while the subjects simply read the words revealed activity in left lateral prefrontal cortex (Brodmann area, BA 47). Activation of left prefrontal cortex was found regardless of whether the words were presented visually or auditorily (in which case the subjects orally repeated the presented nouns to serve as the baseline), thus strengthening the authors’ conclusion of an association between left prefrontal cortex and semantics.

This was an extremely important study because it demonstrated the power of O15 PET and the subtraction method for isolating distinct regions of the brain associated with specific cognitive processes. However, there were two main problems with their conclusion concerning semantics. First, linguistic and cognitive models posit that the meaning of a concrete noun is not unitary, but rather is composed of parts—specifically, knowledge about the physical and functional properties of the object. As such, meaning in the brain has been viewed as a

ALEX MARTIN, LESLIE G. UNGERLEIDER, and JAMES V. HAXBY National Institute of Mental Health, Laboratory of Brain and Cognition, Bethesda, Md.

distributed system, involving many brain regions (e.g., Damasio, 1989). Second, even if semantic networks were confined to a single region, the neuropsychological evidence suggested that the critical area would be the left temporal, not the left frontal, lobe (e.g., Cappa, Cavallotti, and Vignolo, 1981; Hart and Gordon, 1990).

Thus, motivated by these issues, we began to explore the functional neuroanatomy of object semantics in the normal brain using PET. Specifically, we sought to determine whether information about the attributes and features that define an object is stored in the sensory and motor systems that were active during initial learning about that object. This hypothesis, which we call the *sensory/motor model of semantic knowledge* (Martin, 1998), has a long history in behavioral neurology. In fact, turn-of-the-century neurologists commonly assumed that the concept of an object (i.e., its representation) was composed of information about that object learned through direct sensory experience (e.g., Broadbent, 1878; Lissauer, 1890; Freud, 1891; Lewandowsky, 1908, translated in Davidoff and Fodor, 1989).

Retrieving information about object attributes

Given this framework, the critical question was: What object features should be studied? We decided on color and action because there is considerable evidence suggesting that the perception of these features, and knowledge about these features, can be differentially impaired following focal damage to the human brain. For example, acquired color blindness, or achromatopsia, can occur from a lesion of the ventral surface of the occipital lobes (e.g., Damasio et al., 1980; Vaina, 1994; Zeki, 1990), and PET and fMRI studies of normal individuals have confirmed selective activation of this region (specifically, the fusiform gyrus and collateral sulcus in the occipital lobe) during color perception (e.g., Corbetta et al., 1990; Sakai et al., 1995; Zeki et al., 1991). In contrast, a more dorsally located lesion, in the region of the lateral occipital gyrus (located at the border of occipital, temporal, and parietal lobes), can result in impaired motion perception, or akinetopsia (e.g., Zeki, 1991; Zihl et al., 1991; Vaina, 1994), and this location was subsequently confirmed by functional brain-imaging studies of normal subjects (e.g., Beauchamp, Cox, and DeYoe, 1997; Corbetta et al., 1990; Zeki et al. 1991; Watson et al., 1993).

In addition, focal lesions can result in selective deficits in retrieving information about object-associated color and object-associated motion. There are, for example, patients with color agnosia who can neither retrieve the name of a color typically associated with an object nor choose from among a set of colors the one commonly

associated with a specific object (e.g., De Vreese, 1991; Luzzatti and Davidoff, 1994), and other patients have been described with a selective deficit in retrieving verbs (e.g., Caramazza and Hillis, 1991; Damasio and Tranel, 1993). Although the behavioral dissociations exhibited by these patients could be remarkably focal, their brain lesions were not. As a result, the locations of the regions which, when damaged, produced these deficits could not be precisely defined, aside from the suggestion that color agnosias were most commonly associated with damage to the posterior region of the left temporal lobe (see Damasio, Tranel, and Damasio, 1989, for review), whereas verb-generation deficits most commonly were seen in association with damage in and around Broca's area. However, the lesions in these patients often extended posteriorly to include perisylvian cortex (see Gainotti et al., 1995, for review).

The paradigm we used was straightforward. Subjects were presented with black and white line drawings of objects. During one PET scan they named the object, during another scan they retrieved a single word denoting a color commonly associated with the object, and during a third scan they retrieved a single word denoting an action commonly associated with the object. For example, subjects shown a picture of a child's wagon would respond "wagon," "red," and "pull" during the different PET scanning conditions. This last condition is the same as the verb-generation task developed by Petersen, Posner, and colleagues, discussed above.

In agreement with Petersen and co-workers (1988), retrieving object attribute information activated the left lateral prefrontal cortex, over and above that seen for object naming. However, this prefrontal activity did not vary as a function of the type of information subjects retrieved. Rather, the activation was similar for the color and action retrieval conditions, and hence consistent with the idea that left lateral prefrontal cortex is critically involved in retrieval from semantic memory (e.g., Gabrieli, Poldrack, and Desmond, 1998). In contrast, other brain regions were differentially active depending on the type of information retrieved. Importantly, behavioral data collected during the scans (voice response times) confirmed that the color and action retrieval tasks were equally difficult to perform. As a result, differences in pattern of cortical activity associated with these tasks could be attributed to differences in the type of information that the subjects retrieved, rather than to differences in the ease of retrieving the information.

Relative to action verbs, generating color words activated the ventral region of the temporal lobes bilaterally, including the fusiform and inferior temporal gyri, approximately 2–3 cm anterior to regions known to be active during color perception (figure 71.1A; see also color plate

A.**B.**

FIGURE 71.1 (A) Ventral view of the brain showing regions in the temporal lobe more active when subjects retrieved information about object-associated color than object-associated action. (B) Lateral view of the left hemisphere showing regions

more active when subjects retrieved information about object-associated action than object-associated color. (Adapted from Martin et al., 1995.)

45). In contrast, action word generation was associated with a broader pattern of activation that included the classic language zones (left inferior frontal cortex—Broca's area—and the posterior aspect of the left superior temporal gyrus—Wernicke's area) and the posterior region of the left middle temporal gyrus (figure 71.1B; see also color plate 45).¹ The middle temporal activation was located approximately 1–2 cm anterior to the regions active during the motion perception, based on previous PET findings. Thus, retrieving information about specific object attributes activated brain regions proximal to the areas that mediate perception of those attributes.

Replication and converging evidence

COLOR There are now three additional studies reporting an association between the retrieval of object color information and activation of the ventral region of the posterior temporal lobes. In one experiment, subjects generated color words in response to written names of objects, rather than to object pictures (Martin et al., 1995). In

another study, color word generation to pictures of objects was contrasted with generating a color word based on a recently learned, novel, object–color association (Wiggs, Weisberg, and Martin, in press). In a third study, color word generation was evaluated in relation to color naming and color perception (Chao and Martin, 1999). In each study, generating the name of a color commonly associated with an object activated the same region of the ventral temporal cortex, bilaterally in three of the four investigations, located anterior and lateral to the occipital areas active during color perception (figure 71.2A).

Additional evidence that this region may be the site where object-associated color information is stored comes from a PET study of individuals with color-word synesthesia (Paulesu et al., 1995). These individuals, who experience vivid colors when hearing words, showed activity in the left ventral temporal lobe when listening to single words (concrete nouns), whereas normal subjects did not. Moreover, the region active in the synesthetes when they heard words and experienced colors was the same area active when normal subjects retrieved object

A**B**

FIGURE 71.2 (A) Summary of findings suggesting that color information is stored in the ventral temporal lobe, anterior to the regions that mediate color perception. White circles show the location of regions active during color perception (Corbetta et al., 1990; Sakai et al., 1995; Zeki et al., 1991); black circles show the location of regions in the ventral temporal lobes active when subjects generated color words (Martin et al., 1995, two studies; Wiggs, Weisberg, and Martin, 1999; Chao and Martin, 1999); the gray circle on the left hemisphere shows the location of the region active when color-word synesthetes experienced color imagery (Paulesu et al., 1995); the gray circle on the right hemisphere shows the location of the region active in normal subjects during a color imagery task

(Howard et al., 1998). (B) Summary of findings suggesting that motion information is stored in the middle temporal gyrus, anterior to the regions that mediate motion perception. White circles show the location of regions active during motion perception (Corbetta et al., 1990; Watson et al., 1993; Zeki et al., 1991); black circles show the location of the area in the left middle temporal gyrus active when subjects generated action words (Fiez et al., 1996; Martin et al., 1995, two studies; Warburton et al., 1996, four studies; Wise et al., 1991); the gray circle shows the location of activity in the left middle temporal gyrus from an analysis of the pooled data from verb generation experiments conducted at 12 centers participating in the European Union collaborative study (Poline et al., 1996).

color information (figure 71.2A). Thus, the vivid experience of color imagery automatically elicited by auditory stimulation in the synesthetes and the effortful retrieval of information about object color by normal individuals activated a similar region of ventral temporal cortex.

Interestingly, although the word-color synesthesia subjects experienced color when they heard words, they did not show activation in ventral occipital cortex. This finding is in accord with studies in normal subjects of color perception that also evaluated color word (Chao and Martin, 1999) and color imagery generation (Howard et al., 1998)—studies that found activation in the ventral temporal lobe, but not in regions of the occipital cortex active when colors were perceived. These findings, coupled with reports of intact color imagery in an achromatopsic patient (Shuren et al., 1996) and impaired color

imagery in a patient with intact color perception (De Vreese, 1991; case II), suggest that information about object color is stored in the ventral temporal lobe, and that the critical site is close to, but does not include, the areas in occipital cortex that selectively respond to the presence of color.

ACTION There are at least a dozen studies in the literature that have used the action word generation task. As with studies of color word generation, the results have been remarkably consistent. The stimuli used in these studies have included pictures of objects, words presented visually, and words presented auditorily. Subjects have responded aloud in some studies, and silently in others; and they have been required to produce a single response to each item in some studies, and multiple re-

sponses to each item in others. Nevertheless, retrieving information about object-associated action has consistently activated the left middle temporal gyrus, anterior to the region commonly activated during motion perception (figure 71.2B). Moreover, direct electrical stimulation of this region produced greater disruption of action naming than object naming (Corina et al., 1998). Thus, the posterior region of the left middle temporal gyrus appears to be a critical site for storing information about object-associated motion.

Taken together, the findings provide clear and compelling evidence against the idea that information about object attributes and features is stored in a single region of the brain. Rather, these data suggest that this information is distributed throughout the cerebral cortex, and that information about different features is stored in different regions. In addition, the locations of the sites are not distributed randomly, but rather follow a specific plan that parallels the organization of sensory systems, and perhaps motor systems, as well. Thus, within this view, information about object features and attributes such as form, color, and motion would be stored within the processing streams active when that information was acquired, but downstream from (i.e., anterior to) the regions that mediate perception of those attributes.

Automatic activation of semantic object representations

In requiring subjects to focus attention on their knowledge (i.e., stored information) about different object attributes, these findings showed an association with activity in different regions of the posterior temporal lobe. These findings were therefore similar to studies showing modulation of activity in different regions of occipital cortex when subjects attended to different, physically present, features of a stimulus such as its color and motion (e.g., Corbetta et al., 1990). The difference was that in the word generation and imagery studies, attention was paid to stored information about these attributes, rather than to visual properties of the stimulus.

However, as noted earlier, a defining characteristic of patients with category-specific deficits is that they have trouble naming particular types of objects. This finding, in turn, is in accord with models of object naming in which access to stored information about the object is necessary to name it (e.g., Glaser, 1992; Humphreys, Riddoch, and Quinlan, 1988). Simply put, there is no way to get from the lower-order processing of the physically presented object to the object's name without activating prior knowledge about that object. Therefore, a number of investigators have asked whether one could

find evidence for automatic activation of semantic representations during object naming.

The strategy used in these investigations was similar to the word-generation studies reviewed above. The main idea was to try to identify different patterns of activation by pitting different categories against each other. Now, however, instead of focusing attention on information about different attributes, subjects simply named objects from different categories during different brain-imaging scans.

The categories most commonly investigated have been animals (primarily four-legged mammals) and manipulable man-made objects such as tools and utensils. As with the choice of color and action attributes, this choice was motivated by the clinical literature. Specifically, some patients have been described with selective deficits in naming and retrieving information about animals (and often other living things) and others with selective deficits concerning tools (and often other man-made objects), and these are the most common categories affected in patients with category-specific disorders (see Saffran and Schwartz, 1994, for review). One idea as to why this dissociation occurs is based on an argument initially advanced by Warrington and her colleagues (Warrington and McCarthy, 1987): Recognition and naming of individual animals may depend on access to stored information about visual form, whereas recognition and naming of individual tools may depend on access to stored information about function. In fact, as demonstrated by Farah and McClelland (1991), these relationships are evident in standard dictionary definitions. For example, the word *camel* is defined by what it looks like—specifically, as being large, having a humped back, a long neck, and large feet; the word *wrench*, however, is defined by its function—specifically as being used for holding and turning other objects (cf. *Webster's New World Dictionary*, 3d edition, 1988).

Thus the central idea is that we need to utilize information about relatively subtle differences in visual form to distinguish one four-legged animal from another. We know animals, and we distinguish among them by their physical features—primarily shape and, to a lesser extent, color and pattern (consider, for example, the difference between a leopard, a tiger, and a jaguar, or between a horse, a donkey, and a zebra). But tools are different. Although tools clearly have different shapes, and there is certainly a relationship between their form and function, the relationship between a tool's physical shape and its name is simply not as tightly constrained as the relationship between the physical shape of an animal and its name. Thus, for animals, there is an invariant relationship between name and form, whereas for tools there is an invariant relationship between name and function.

An important point to be addressed, then, is the meaning of “function” in the present context. In some formulations the term *function* is used to designate a large number of characteristics concerned with an object’s use. As such, the information is characterized as more “abstract,” “conceptual,” “verbal,” and “semantic” than the visual form-based information needed to distinguish among animals (e.g., Riddoch and Humphreys, 1987; and see discussion in Tyler and Moss, 1997). In contrast, the position proposed here is that the information about object function needed to support tool recognition and naming is information about the patterns of visual motion and patterns of motor movements associated with the actual use of the object. As such, this information is as dependent on sensory experience as is information about the visual form. The difference is that functional information is derived from motor movements, and visual processing of motion, rather than visual processing of form.

In our first study we asked subjects to silently name line drawings of real objects, each presented for a brief period of time (180 ms) (Martin et al., 1996). For one scan the objects were four-legged animals, and for another the objects were common tools and utensils. Subjects also attended to visual noise patterns, and stared at novel, nonsense objects during other scans to provide baselines. First, as expected, relative to viewing nonsense objects, naming real objects was associated with activity in the left inferior frontal lobe (i.e., Broca’s area), thus indicating that the subjects named the objects to themselves, as instructed. In addition, naming animals and naming tools both produced strong, bilateral activity in the posterior region of the fusiform gyrus of the temporal lobe, greater on the left than on the right. This failure to find category-related differences in the ventral temporal lobe was somewhat problematic, and we will revisit this issue.

In addition to these regions that were active during both animal and tool naming, other brain regions were differentially activated by animal and tool naming. First, naming tools was associated with activity in the left middle temporal gyrus, in the same region that was active in the previously discussed action verb generation studies. Tool naming was also associated with activity in the left premotor cortex, in the same region active when subjects imagined grasping objects with their dominant hand (Decety et al., 1994). Taken together, these findings were consistent with the idea that identifying individual tools was dependent on accessing information about object-associated patterns of visual motion, stored in the posterior region of the left middle temporal gyrus, and accessing information about object-associated patterns of motor movements stored in left premotor cortex (Martin et al., 1996).

In contrast, relative to naming tools, naming animals was associated with activation of medial occipital cortex. This activation was bilateral, but stronger on the left than the right. We suggested that this occipital activity reflected top-down activation, which would occur whenever information about visual features is needed to distinguish between category members. Thus, there were two parts to this argument. First, that animals are defined by their physical form, and that in order to name them we need to gain access to this stored-form information. Second, when the differences between members of a category are determined by relatively subtle differences in form (as in the previously mentioned animal examples), the occipital cortex is brought into play to help to visualize (image) these differences. Thus, the second part of the argument was the same as the idea proposed by Kosslyn (e.g., Kosslyn, Thompson, and Alpert, 1995; Kosslyn et al., 1995) with regard to involvement of occipital cortex in visual imagery tasks that require imaging fine details of an object or scene. But while in Kosslyn’s tasks subjects are explicitly asked to create and manipulate an image, in this formulation the image would be generated automatically, and often outside of awareness (and see Shulman et al., 1997, for additional evidence for top-down modulation of medial occipital cortex associated with other types of visual processing tasks).

Replication and converging evidence

RECOGNITION OF ANIMALS AND THE MEDIAL OCCIPITAL CORTEX Of course, the alternative, and more straightforward interpretation of the medial occipital activation when naming animals is that it reflects differences in the visual complexity of the stimuli. Under this view, pictures of animals produce greater activity in medial occipital cortex because the line drawings depicting these objects were more visually complex than the line drawings depicting tools. Similarly, a patient could have greater difficulty naming animals than tools because the pictures are more visually complex, and less familiar, than pictures of tools and other manipulable objects, such as kitchen utensils (see Gaffan and Heywood, 1993; Stewart, Parkin, and Hunkin, 1992, for supportive data; Farah, Meyer, and McMullen, 1996, for counter-evidence). Therefore, we attempted to rule out stimulus differences in visual complexity by transforming each of the object pictures to a silhouette, thereby eliminating differences between animal and tool pictures with regard to internal visual detail. This transformation produced a modest slowing of naming speed and increased errors, but importantly, eliminated the speed and accuracy advantage for tool naming relative to animal naming found in the study using line drawn stimuli.

Silent naming of the object silhouettes produced the same differential patterns of activation for animal and tool naming found in the first study, including greater activation of the left medial occipital region when naming animals than when naming tools (Martin et al., 1996). Greater medial occipital activation for animal than tool stimuli was also reported by Perani and colleagues (1995) using a semantic, exemplar match paradigm, and by Damasio and colleagues (1996) using an object naming task. Thus, these findings were more consistent with a top-down explanation than with a bottom-up explanation for the association of medial occipital activation and naming pictures of animals.

Additional, and more direct, evidence for the differential patterns of activation associated with identifying and naming animals and tools comes from a recent study of patients with category-specific knowledge disorders. Tranel, Damasio, and Damasio (1997) identified 28 individuals with focal brain lesions that had impaired recognition and naming of animal pictures. Unlike the patients in their previous report (Damasio et al., 1996) of category-specific naming, but not knowledge, disorders, the patients included in the 1997 study failed to provide evidence of intact knowledge about the stimuli they could not name. For example, they were unable to provide accurate, detailed descriptions of the items, thus suggesting that they had a semantic, category-specific deficit. Each of the 28 patients had a lesion that included the medial aspect of the occipital lobe. In 14 of the cases, the lesion was lateralized to the left hemisphere; in the remaining cases, the lesion was lateralized to the right. These were not the first cases with unilateral occipital lesions and category-specific disorders. For example, Nielsen (1958) described six patients with what he termed a selective agnosia for animate objects, all of whom had unilateral occipital lesions, mostly on the left. Thus the functional brain imaging studies of normal subjects and studies of patients with focal brain lesions provide converging evidence that the medial occipital cortex is more involved in recognizing and naming animals than tools (figure 71.3A,B; see also color plate 46), and that its role in mediating this ability is not easily attributed to bottom-up processing of stimulus characteristics.

RECOGNITION OF TOOLS AND THE LEFT MIDDLE TEMPORAL GYRUS The Tranel, Damasio, and Damasio (1997) study also identified eight patients with impaired recognition and naming of tools. The lesions in those patients all included the posterior region of the left middle temporal gyrus, in nearly the same region active during tool naming, and action word generation (figure 71.3C,D). Thus, these patients provided converging evi-

dence that the left posterior middle temporal gyrus is necessary for naming tools, but not animal pictures. In addition, in a PET study of verbal fluency to orally presented category cues, Mummery and colleagues (1996) found activation of this same region of the left middle temporal gyrus when normal subjects simply generated the names of tools and other manipulable objects, such as weapons and toys, relative to generating the names of animals, vegetables, and fruits. Therefore, these studies provide additional evidence consistent with the idea that this region of the left temporal lobe may be where information about object associated motion is stored.

RECOGNITION OF TOOLS AND LEFT PREMOTOR CORTEX Although the Tranel, Damasio, and Damasio (1997) study did not identify patients with anterior lesions, there are reports of at least five patients with lesions that included the left frontal lobe who were more impaired with man-made objects than animals (reviewed in Gainotti et al., 1995). However, as is common with patients with category-specific disorders, the lesions were large, and included the left parietal lobe (all five cases), as well as the left temporal lobe (three of five cases). Therefore, although consistent with the idea that the left premotor region may be involved in naming and knowing about tools, these cases do not provide evidence for the specific involvement of left premotor cortex.

Supportive evidence, however, has been provided by other functional brain imaging studies. Activation of the left premotor site associated with naming tools, but not animals, was found when subjects imagined grasping objects with their right hand (Decety et al., 1994; Grafton et al., 1996), imagined performing a sequence of joystick movements with their right hand (Stephan et al., 1995; activation of the left middle temporal gyrus was also reported in this study), and silently generated action words to pictures of tools (Grafton et al., 1997) (figure 71.4).

Interestingly, studies by Rizzolatti and colleagues have identified neurons in the inferior region of monkey premotor cortex (area F5) that respond both during the execution of a movement, and when observing the movement performed by others. These and related findings have led to the suggestion that these neurons represent observed action, and form the basis for the understanding of motor events (Rizzolatti et al., 1996a). Thus, it may be that the left premotor region identified in the above-noted functional brain imaging studies carries out a similar function—specifically, storing information about the patterns of motor movements associated with the use of an object. If so, the fact that naming tools, but not animals, activates this region further

FIGURE 71.3 (A) View of the medial surface of the left hemisphere showing the region of activation in the medial occipital lobe when subjects silently named drawings of animals relative to naming drawings of tools (adapted from Martin et al., 1996). (B) View of the medial surface of the left and right hemispheres showing the location of lesions in 28 subjects that had impaired recognition and naming of drawings of animals (adapted from Tranel, Damasio, and Damasio, 1997). (C) View

of the lateral surface of the left hemisphere showing regions active in the premotor cortex and middle temporal gyrus when subjects silently named drawings of tools relative to naming drawings of animals (adapted from Martin et al., 1996). (D) View of the lateral surface of the left hemisphere showing the location of lesions in 8 subjects that had impaired recognition and naming of drawings of tools (adapted from Tranel, Damasio, and Damasio, 1997).

suggests that this information is automatically accessed when manipulable objects are identified. Indeed, while some neurons in monkey F5 responded when movements were observed, other neurons responded as soon as a graspable object was visually presented (see Jeanerod et al., 1995 for review).

Posterior temporal cortex revisited: The representation of object form and motion

As noted previously, in the study by Martin and colleagues (1996), the ventral region of the posterior temporal lobe was activated bilaterally, and to an equal extent by animal and tool naming. Perani and associates (1995) also reported activity in the ventral temporal region for both animals and tools; but again, this region

was not differentially involved in processing objects from one category or the other. These findings were problematic for two reasons. First, if greater activation of the medial occipital lobe when naming animals than tools results from top-down modulation, there should be differentiation more anteriorly in the ventral object-processing stream to drive this process. If there is no anterior site that responds more during animal than tool naming, then where is the top-down influence originating from? Second, although, as reviewed above, there have been reports of patients with unilateral occipital lesions that had category-specific impairment for animals and other animate or living objects, many other cases have had lesions confined to the temporal lobes, often as a result of herpes encephalitis (see Ferreira, Giusiano, and Poncet, 1997, for recent cases; and see Gainotti et

FIGURE 71.4 Summary of findings suggesting that information about patterns of motor movements associated with the use of objects is stored in left premotor cortex. Black circles show the location of regions active when subjects silently named line drawings and silhouettes of tools relative to naming animals (Martin et al., 1996). The white circle shows the location of the region active when subjects silently generated action words in response to pictures of tools (Grafton et al., 1997). Gray circles show locations active when subjects imagined grasping objects with their right hand (Decety et al., 1994; Grafton et al., 1997), and imagined a sequence of joystick movements (Stephan et al., 1995).

al., 1995, for review). The functional brain imaging data indicated that the posterior region of the middle temporal gyrus was selectively involved in recognizing and naming tools, and the human lesion data showed that a lesion in this region could produce a category-specific deficit for tools (Tranel, Damasio, and Damasio, 1997). However, the functional brain imaging data have not identified a region of the temporal lobe selectively involved in processing and knowing about animals, even though the human lesion data suggest that such a region, or regions, should be found.

One possibility is that this discrepancy between the functional brain imaging and lesion data is a result of the limited spatial resolution of PET. Perhaps there is a consistent category-related topology in the ventral region of the temporal lobe, but the sites are situated too close to one another to be visualized by PET. Evidence in support of this idea has been provided by studies of epileptic patients with chronically implanted electrodes, and fMRI studies of normal subjects. These studies have identified relatively small regions in the ventral temporal lobe that selectively respond to the presentation of different types of stimuli, such as human faces (e.g., Allison et al., 1994; Haxby et al., 1997; Kanwisher, McDermott, and Chun, 1997; McCarthy et al., 1997; Puce et al., 1995), letters (Allison et al., 1994; Puce et al., 1995; Polk and Farah, 1998), houses (Haxby et al.,

1997), chairs (Ishai et al., 1997), and representations of the local visual environment (Epstein and Kanwisher, 1998).

The most consistent finding has been the selective activation of the more lateral aspect of the fusiform gyrus, usually stronger on the right than on the left, in response to human faces. In addition, using fMRI, Haxby and colleagues have found that whereas the lateral fusiform is more responsive to faces, the more medial aspect of the fusiform gyrus is more responsive to pictures of houses (Haxby et al., 1997; Ishai et al., 1997). This topological arrangement was highly consistent across subjects, variation in stimuli (i.e., photographs and line drawings), and task (passive viewing, delayed match to sample). Moreover, a similar, highly consistent topology in the fusiform gyrus has also been revealed for the processing of animals and tools across several different paradigms (passive viewing, delayed match to sample, and naming) (Chao et al., 1998a,b).

First, pictures of animals produced a robust response in essentially the same region activated by human faces (i.e., lateral fusiform gyrus, bilaterally), regardless of whether the animal's face was visible or not (Chao et al., 1998b). Second, in contrast to human faces, animal pictures also elicited weaker, yet significant, bilateral activity in the more medial aspect of the fusiform gyrus that responded most strongly to houses; faces, in contrast, produced essentially no activity in this region.² Third, relative to animals, tools were associated with greater activation of the more medial aspect of the fusiform gyrus that overlapped with, but was not identical to, the medial fusiform region most responsive to houses (Chao et al., 1998a).

Therefore, in contrast to the PET data, fMRI revealed distinct and consistent patterns of activity for animals and tools in the ventral region of the temporal lobe, bilaterally. Viewing, matching, and naming pictures of animals were associated with stronger activation of the lateral aspect of the fusiform gyrus than was performing these tasks with pictures of tools, whereas tools produced greater activity in the more medial aspect of the fusiform gyrus than did animals.

It is important to note, however, that in these studies no area was identified that responded exclusively to one class of objects and not others. Rather, each object type activated a relatively broad region of the fusiform gyrus (albeit more narrowly for faces), but the peaks of these activations were centered on different parts of the fusiform gyrus. Therefore, rather than being organized by object category, per se, this pattern of results was more consistent with the idea that this cortex is tuned to different object features that members of a category have in common. The nature of these features remain to be

determined. However, because the fusiform gyrus is part of the ventral, object-processing stream, a likely possibility is that this region may be tuned to features of object form. Thus, information about object form may be stored in the fusiform gyrus and other regions of ventral temporal cortex, downstream from the regions of occipital cortex that mediate form perception. Moreover, this cortex may have a consistent topological arrangement based on stored features of form shared by objects in the same category (i.e., faces, houses, animals, tools).

Animals and tools were also associated with activations of neighboring regions. Consistent with the PET data, tools were associated with activity in the middle temporal gyrus in most subjects, stronger on the left than on the right (i.e., the same region active when subjects retrieve action verbs). Animals and faces, however, were associated with activation in the superior temporal sulcus (STS) in about half the subjects, usually stronger on the right than on the left (also reported by Kanwisher, McDermott, and Chun, 1997).

Single-cell recording studies in awake monkeys have shown activity in STS when the monkeys were viewing faces and face components, and when the monkeys observed motion of people and other monkeys (see Desimone, 1991, for review). Consistent with these findings, human brain imaging studies have revealed STS activity when viewing faces (Kanwisher, McDermott, and Chun, 1997), viewing mouth and eye movements (Puce et al., 1998), and when observing human movements (Bonda et al., 1996; Rizzolatti et al., 1996b). Thus it may be that the STS is involved not only in the perception of biological motion, but also in storing information about biological motion, perhaps in different parts of this region. If so, the fact that viewing animals and faces activates a portion of STS suggests that this information may be necessary, or at least available, to support processing of these stimuli. Similarly, the consistent finding of left middle temporal gyrus activity in response to pictures of tools suggests that information about motion properties of nonbiological objects may be stored in this region of the temporal lobe.

Finally, as was the case for the ventral temporal lobe, the lateral temporal cortex may not be organized by object category, per se, but rather may be tuned to different object features that members of a category have in common. Again, although the nature of these features remain to be determined, the proximity of these activations to the more posterior motion processing areas suggests that this region may be tuned to features of object motion. Yet-to-be-determined properties associated with biological motion produce activity centered around the STS, whereas properties of man-made object-associated

motion produce activity centered around the middle temporal gyrus and inferior temporal sulcus (figure 71.5).

Summary: Multiple, distinct regions for processing and storing information about object attributes

Studies of patients with focal cortical lesions and the findings from functional brain imaging of the intact human brain provide converging evidence for the idea that recognition and naming of different types, or classes, of objects, such as animals and tools, are associated with different networks of discrete cortical regions. Tasks dependent on identifying and naming pictures of animals are associated with activity in the more lateral aspect of the fusiform gyrus, medial occipital cortex, and STS. These activations may be related to the automatic activation of stored information about object form, visual detail, and biological motion, respectively. In contrast, identifying and processing pictures of tools were associated with activation of the more medial aspect of the fusiform gyrus, left middle temporal gyrus, and left premotor cortex; and these sites may be related to the automatic activation of stored information about object form, nonbiological motion, and object use-associated motor movements, respectively.

The important point here is that regardless of the functions or computations ultimately attributed to these regions, these data suggest that the proper level of analysis for understanding semantic object representations is at the level of features, not at the level of whole-object concepts like animals and tools (for an alternative view, see Caramazza and Shelton, 1998, and Caramazza, this volume).

Finally, although much of the evidence reviewed here concerns processing of pictures of objects, it is assumed that these networks will be active regardless of the physical characteristics of the stimulus (picture or word) or modality of presentation (visual or auditory).

Conclusion: Semantic primitives

If there is one aspect of a semantic system that invites consensus, it is that the system must be productive. And, in order to be productive, it must be compositional (e.g., Fodor and Lepore, 1996). In this chapter we have reviewed evidence that suggests what some of those components may be. These components can be thought of as prelexical, semantic primitives for processing and storing information about form, color, motion, and movement (Martin, 1998). This list is not meant to be exhaustive. A good case could be made for other semantic primitives concerned with space, time, number, and

FIGURE 71.5 Schematic representation of posterior temporal cortex proposed to be tuned to features of object form (ventral surface) and motion (lateral surface) shared by members of a category. It is assumed that information is stored in this region according to some as-yet undetermined, but probably innate, properties. It is further assumed that this region would be ac-

ffective valence. These should be thought of as innately determined, neurobiologically plausible mechanisms that function in the service of meaning. Such a scheme, on the level of features and attributes, provides us with combinatorial power out of which different, and finer shades of meaning can be created.

NOTES

1. Re-analysis of the initial study by Petersen and colleagues (1988) indicated that the posterior region of the left middle temporal gyrus was active during their verb generation condition. This activation was not reported because it was below the threshold for statistical significance. Subsequent studies of verb generation by these investigators showed robust activation of the left middle temporal region when the rate of stimulus presentation was slowed from 1 per second (used in Petersen et al., 1988) to 1 per 1.5 seconds, thus giving subjects more time to retrieve each verb (see Raichle et al., 1994, and Fiez et al., 1996).
2. The differential patterns of activity in the lateral and medial fusiform gyrus in response to pictures of animals and human faces may provide a clue to why patients can present with a selective deficit for faces, and not other types of objects such as animals. It is not because the lateral region of the fusiform gyrus processes only faces; rather, it is because faces, as stimuli, are more focally represented than other classes of objects. Thus, when the lateral fusiform is damaged, face processing suffers to a greater extent than the processing of other object types.

tive in support of object identification, regardless of stimulus format (object or word) or modality of input. PHG, parahippocampal gyrus; CS, collateral sulcus; FG, fusiform gyrus; ITG, inferior temporal gyrus; ITS, inferior temporal sulcus; MTG, middle temporal gyrus; STS, superior temporal sulcus.

72 The Organization of Conceptual Knowledge in the Brain

ALFONSO CARAMAZZA

ABSTRACT Theories of how conceptual knowledge is organized in the brain are evaluated. Three types of evidence are considered: the patterns of cognitive disorders following brain injury, computer simulations of these disorders, and functional neuroimaging results. However, the focus is on the neuropsychological evidence. The results show that the categories of animals, fruits and vegetables, artifacts, and body parts can each be damaged or spared selectively. It is argued that this pattern of dissociations and other aspects of these patients' performance are incompatible with theories that propose that conceptual knowledge is organized into several modality-specific subsystems. The proposal is made that conceptual knowledge is organized into broad domains of knowledge reflecting evolutionary adaptations.

How is conceptual knowledge organized in the brain? What are the principles that govern its organization? Various proposals have been made. The most widely adopted principle is that conceptual knowledge is distributed over several modality-specific subsystems. On this view, the visual properties of an object are represented in a visual semantic subsystem, its auditory properties (e.g., its characteristic sounds) in an auditory semantic subsystem, its action properties in an action semantic subsystem, and so on (see, for example, Allport, 1985). I will refer to this principle as the "modality-specific principle." Another proposal is that what determines the organization of conceptual knowledge is the relative strengths of the associations among the properties that characterize an object, irrespective of their sensory/motor content (see, for example, Caramazza et al., 1990; Riddoch et al., 1988). On this view, properties that are highly correlated (e.g., having a particular shape and a particular function) will tend to be processed together and are likely to be represented in close proximity in the brain. I will refer to this principle as the "correlated-structure principle." A radically different proposal is that conceptual knowledge is organized into several broad domains (Caramazza and Shelton, 1998). The determining principle here is an evolutionary one: It is assumed that evolutionary pressures resulted in dedicated brain

mechanisms for processing specific classes of objects (Gelman, 1990; Premack, 1990; Hauser, 1997). Plausible candidates are the categories of conspecifics, animals, and plant life (and perhaps artifacts¹). I will refer to this principle as the "domain-specific principle."

These principles are not mutually exclusive. It is possible that more than one principle is at play in determining the organization of knowledge in the brain. For example, it could turn out that the organization of conceptual knowledge is determined both by the domain-specific and the correlated-structure principles. However, extant proposals have tended to favor one or another principle to the exclusion of others. In this chapter I review the major theories of conceptual representation that have resulted from the adoption of these principles, and the empirical evidence that has been adduced in their support. I focus primarily on a widely held theory that is based on the modality-specific principle. I show that, despite its popularity, the theory is not well supported by empirical evidence. Alternative accounts based on the correlated-structure principle and the domain-specific principle will be considered briefly.

Three types of evidence have been used to inform theories of conceptual organization in the brain: the patterns of cognitive disorders following brain injury, computer simulations of these disorders, and functional neuroimaging results. However, most of the evidence to date consists of the patterns of dissociations of functions observed in brain-damaged patients. Two neuropsychological phenomena have been especially important in this regard: modality-specific and category-specific naming/comprehension disorders. Accordingly, this discussion of the organization of conceptual knowledge focuses primarily on the implications from the neuropsychological evidence, but will also briefly consider the computational modeling and functional neuroimaging evidence.

Modality-specific semantics

The idea that semantics is not a unitary system but a collection of modality-specific subsystems has recently emerged as the dominant view in the cognitive

ALFONSO CARAMAZZA Department of Psychology, Harvard University, Cambridge, Mass.

neurosciences. In its original formulation, theories of modality-specific semantics distinguished between visual and verbal semantic subsystems (e.g., Beauvois, 1982; Paivio, 1971; Warrington, 1975). More recent formulations (e.g., Allport, 1985; Shallice, 1987) have included other modality-specific subsystems. But the core components of the theory are the visual and the functional/associative subsystems: The visual semantic subsystem stores information about the visual properties of objects (e.g., cars have wheels; donkeys have legs) and the functional/associative semantic subsystem stores information about the uses of objects, where they might be found, and other nonsensory properties (e.g., birds lay eggs; chairs are for sitting; whales live in water). I will refer to this theory of the organization of conceptual knowledge in the brain as the “sensory/functional theory” (SFT).

NEUROPSYCHOLOGICAL EVIDENCE: MODALITY-SPECIFIC NAMING DISORDERS Modality-specific naming disorders played an important role in the original formulation of the SFT but have since been given less emphasis. The relevant observation is the following: There are neurological patients who show greater difficulty in naming objects presented in one modality relative to other modalities. The classical form of the disorder is known as optic aphasia—a selective disturbance in naming visually presented objects despite intact visual processes and intact ability to name objects presented in other modalities. These patients typically present with left occipital cortical and subcortical lesions extending to the posterior part of the corpus callosum, effectively disconnecting the left hemisphere from visual input. A number of patients have been described with this general profile of performance and brain lesions (e.g., Coslett and Saffran, 1989; Hillis and Caramazza, 1995; Lhermitte and Beauvois, 1973).

Beauvois (1982; see also Shallice, 1987) interpreted the modality-specific dissociation in such patients as reflecting a disconnection between intact visual and verbal *semantic* subsystems. The verbal semantic subsystem was assumed to be intact because optic aphasics produce language normally, show normal ability to understand spoken words, and can name normally in response to verbal definitions. The visual semantic subsystem was assumed to be intact because the patients are supposedly able to mime the use of objects they cannot name. The latter performance was also taken as an indication that access to visual semantics from visual inputs was normal. Thus, optic aphasia could be construed as providing evidence for modality-specific semantics. Other types of modality-specific naming/semantic deficits have similarly been interpreted as support for a modality-specific, multiple semantics theory (e.g., McCarthy and

Warrington, 1988). However, it has been argued that the existence of modality-specific anomias does not require postulating distinct semantic subsystems. These disorders are more plausibly and parsimoniously explained as reflecting a partial disconnection between modality-specific *structural* descriptions of objects and a modality-neutral, unitary semantic system (for detailed discussion see Caramazza et al., 1990; see also Rapp, Hillis, and Caramazza, 1993; Riddoch et al., 1988). Thus, the evidence from modality-specific naming deficits does not distinguish between multiple (modality-specific) and unitary semantics theories and will not be discussed further here.

NEUROPSYCHOLOGICAL EVIDENCE: SEMANTIC CATEGORY-SPECIFIC DISORDERS The more intriguing result bearing on the organization of conceptual knowledge in the brain is the existence of semantic category-specific deficits.² These deficits are characterized by the disproportionate impairment (or sparing) of a semantic category. For example, a patient might have severe difficulties in naming living things but relatively preserved ability in naming all other objects. The importance of the existence of these deficits for informing theories of the organization of conceptual knowledge in the brain was first forcefully emphasized by Elizabeth Warrington and her collaborators, who also reported the first thoroughly investigated cases of such deficits. Warrington, Shallice, and McCarthy reported a series of patients who were disproportionately impaired either in naming and recognizing living things (Warrington and Shallice, 1984) or nonliving things (Warrington and McCarthy, 1983, 1987). Since these seminal reports, many other cases of category-specific deficits have been reported. Most reports have concerned the disproportionate impairment of living things in patients with neurological disease affecting the inferior temporal lobe (e.g., Basso, Capitani, and Laiacina, 1988; DeRenzi and Lucchelli, 1994; Silveri and Gainotti, 1988; see Gainotti et al., 1995, for review). However, there are also reports of disproportionate impairment of nonliving things (e.g., Hillis and Caramazza, 1991; Sacchett and Humphreys, 1992). Although these contrasting patterns of deficits would seem to provide *prima facie* evidence for some type of categorical organization of conceptual knowledge in the brain, Warrington and her collaborators argued, instead, that they provide evidence for a modality-specific organization of the semantic system.

The phenomenon of category-specific deficits could be used to inform claims about the organization of conceptual knowledge only if it could be demonstrated that (at least some of) these deficits concern the semantic system and not merely perceptual processes involved in

recognizing objects or output processes involved in lexical selection. This condition is easily met by a number of well-studied cases (e.g., Lambon-Ralph et al., 1998; Samson, Pillon, and De Wilde, 1998). The performance of patient EW (Caramazza and Shelton, 1998) is typical of such cases.³

A 72-year-old woman at the time of testing (in 1996), EW had suffered (in 1988) a left cerebral vascular accident involving the left posterior frontal and parietal lobes. When she was first tested in our laboratory, she was only mildly aphasic but demonstrated difficulties naming the animals in a screening test for aphasia. Detailed investigation of her naming and comprehension abilities documented a highly selective deficit for animals. In naming the Snodgrass-Vanderwart (1980) pictures, she named all fruits and vegetables correctly (24/24) and 109/118 (92%) items in various artifact categories (tools, furniture, etc.). However, she was able to name only 16/47 (34%) animals. Her difficulties with animals could not be attributed to such factors as frequency, familiarity, or visual complexity (Funnell and Sheridan, 1992; Stewart, Parkin, and Hunkin, 1992).

EW's difficulties in processing animals were not restricted to naming. She was also severely impaired in distinguishing real from unreal animals (chimeras) and in deciding which of two heads or parts of an object went with a body. In both tasks she was severely impaired with animals (object decision: 60% correct; part decision: 70% correct) but performed normally with artifacts. Her difficulties also extended to the comprehension of property statements (e.g., a horse has four legs). Collapsing across several attribute judgment tasks, EW performed very poorly with animals (425/601; 70.7% correct) but normally with artifacts (434/445; 97.5% correct). The fact that EW's difficulties in processing the category of animate objects were observed in naming tasks, object decision tasks, and property judgment tasks invites the inference that the functional locus of the damage is at the level of the semantic system—the only component that is shared across all three tasks. Thus, we can conclude that EW has a category-specific *semantic* deficit, and we can proceed to explore the implication of this conclusion (and similar conclusions for related cases) for theories of the organization of conceptual knowledge.

Semantic category-specific deficits How can category-specific semantic deficits be construed as support for the SFT? The argument is not straightforward and depends on crucial assumptions about the relative importance of visual and functional/associative properties in determining the meaning of living and nonliving things. These assumptions are that visual properties are more important

than functional/associative properties in determining the meaning of living things and that functional/associative properties are more important than visual properties in determining the meaning of nonliving things. That is, it is assumed that our ability to distinguish among living things depends far more on our knowledge of the visual attributes of the members of the category than on our knowledge of their functional/associative properties. Similarly, it is assumed that we distinguish among the members of nonliving things primarily through our knowledge of their functional/associative properties. Given these assumptions, selective damage to the visual semantic subsystem would be expected to result in disproportionate impairment for the category of living things, while selective damage to the functional/associative semantic subsystem would result in disproportionate impairment for the category of nonliving things. Thus, the SFT could in principle account for the occurrence of category-specific deficits. However, these deficits would have to take a particular form. The types of category-specific deficits that are expected to occur should not strictly honor folk taxonomic boundaries (e.g., impairment restricted only to animals). Rather, the deficits should involve clusters of categories reflecting the relative importance for each category of the damaged modality-specific subsystem. For example, damage to the visual semantic subsystem should result in impairment of all categories for which visual information plays an important role distinguishing among their members (e.g., on some accounts this will include at least animals, fruits and vegetables, and musical instruments).

The SFT also makes a highly specific prediction. Since category-specific deficits are the result of selective damage to one of the modality-specific semantic subsystems—the visual or the functional/associative subsystems for living and nonliving things, respectively—it follows that these deficits should be associated with disproportionate impairment for either visual or functional/associative knowledge. In other words, the SFT predicts that category-specific deficits for living things should co-occur with disproportionate difficulty for the visual attributes of objects, and that selective deficits for nonliving things should co-occur with disproportionate impairment for the functional/associative properties of objects. A corollary of this prediction is that damage to either the visual or the functional/associative semantic subsystem must result in selective difficulties for living or nonliving things, respectively. In other words, the SFT predicts a necessary co-occurrence of impairments for kinds of information (visual or functional/associative) and types of semantic categories (living and nonliving).

The early accounts of category-specific deficits seemed to confirm the expectations derived from the

SFT. These reports appeared to confirm both the prediction that category-specific deficits involve clusters of categories defined by their dependence on a particular type of information (e.g., visual properties) and the prediction that selective deficits for living things are associated with disproportionate difficulty for the visual properties of objects. A recent review of semantic category-specific deficits concluded that the forms of this disorder support the SFT (Saffran and Schwartz, 1994). However, critical scrutiny of the early reports and the results of tightly controlled recent investigations cast serious doubt on this conclusion (see Caramazza and Shelton, 1998, for detailed review).

What are the categories of category-specific deficits? Although the early cases of category-specific deficit were characterized as disorders of either the category of living things or nonliving things, the actual pattern of impaired and spared categories was more complex than a simple living/nonliving dichotomy. One of the paradigm cases of category-specific deficit for living things—JBR (Warrington and Shallice, 1984)—was also impaired in processing the categories of foods, musical instruments, precious stones, diseases, cloths, and metals. Other patients have shown similarly complex configurations of category deficits. For example, a number of patients have been shown to be impaired in processing living things and foods (e.g., De Renzi and Lucchelli, 1994; Sheridan and Humphreys, 1993; Silveri and Gainotti, 1988), and others in processing living things and musical instruments (e.g., Silveri and Gainotti, 1988).⁴

Warrington and Shallice interpreted this pattern of co-occurrence of category deficits as reflecting damage to a semantic subsystem that is important for distinguishing among members of the affected categories. That is, the co-occurrence of impairments for the categories of living things, musical instruments, and foods is assumed to reflect the fact that visual properties are especially important in distinguishing among the members of these categories, whereas functional/associative attributes are especially important in distinguishing among the members of the spared categories (e.g., tools, furniture, vehicles, etc.). On this view, damage to the visual semantic subsystem would result in impairment of the categories of animals and plant life as well as musical instruments and foods (and other categories that are similarly dependent on visual properties).

There are two problems with this conclusion. One problem is that it is not obvious that the observed association of category-specific deficits is explicable by postulating damage to the visual semantic subsystem. That is, it is not obvious that visual as opposed to functional/associative attributes are more important for distin-

guishing among members of the categories of musical instruments and foods (think of what distinguishes scrambled eggs from hamburgers or pianos from drums, piccolos, and violins). Nor is there independent empirical confirmation for this contention. More problematic for the SFT is the fact that category-specific deficits dissociate along lines that are not expected from the claim that the deficits reflect damage to a common semantic subsystem. There are reports of patients with category-specific deficits for animals (and fruits and vegetables, in some cases) but not foods (Hart and Gordon, 1992; case P.S.: Hillis and Caramazza, 1991; Laiacona, Barbarotto, and Capitani, 1993); there are patients who are impaired in naming foods but not animals (case J.J.: Hillis and Caramazza, 1991); there are patients who are impaired for the categories of animals and foods but not musical instruments (De Renzi and Lucchelli, 1994); and so on. And there are even finer-grained dissociations of category-specific deficits. For example, there are now several reports that show that the categories of animals and of fruits and vegetables can be damaged independently of each other (Caramazza and Shelton, 1998; Farah and Wallace, 1992; Hillis and Caramazza, 1991; Hart, Berndt, and Caramazza, 1985; Hart and Gordon, 1992). Thus the claim that certain semantic categories are damaged together because of their common dependence on a modality-specific semantic subsystem is not supported.

Is there a necessary dependence between type of semantic category-specific deficit and subtype of semantic information that is damaged? The core empirical prediction of the SFT is that selective deficit for living things necessarily co-occurs with disproportionate impairment for the visual attributes of objects (Farah and McClelland, 1991; Gainotti and Silveri, 1996). Early reports of cases of category-specific deficits seemed to confirm this expectation. Patients with category-specific deficits for living things were also reported to be disproportionately impaired in processing the visual attributes of objects (e.g., Basso, Capitani, and Laiacona, 1988; Farah et al., 1989; Silveri and Gainotti, 1988). However, these studies have been criticized on methodological grounds (see Caramazza and Shelton, 1998). For example, Farah and co-workers reported a patient with a category-specific deficit for living things who performed more poorly in verifying property statements concerning visual (e.g., ducks have long ears) than functional/associative attributes (e.g., roses are given on Valentine's Day). Furthermore, this effect was more marked for living than nonliving things. However, inspection of the data shows that normal subjects were also disproportionately worse with the visual attributes of living things.

TABLE 72.1
Percent correct performance for visual and functional/associative property judgments by patients with category-specific deficits for living things

Patient	Living		Nonliving	
	Visual	Functional	Visual	Functional
EW (Caramazza and Shelton, 1998)	67	74	96	99
GR (Laiacona, Barbarotto, and Capitani, 1993)	55	58	91	84
FM (Laiacona, Barbarotto, and Capitani, 1993)	73	69	96	96
JEN (Samson et al., 1998)	42	51	75	83
DB (Lambon-Ralph et al., 1998)	69	69	100	100
RC (Moss et al., 1998)	69	70	79	90

Far more problematic for the SFT are recent reports showing that patients with category-specific deficits for living things are equally impaired in processing visual and functional/associative attributes when these are matched for difficulty (Caramazza and Shelton, 1998; Laiacona, Barbarotto, and Capitani, 1993; Laiacona, Capitani, and Barbarotto, 1997; Lambon-Ralph et al., 1998; Moss et al., 1998; Samson, Pillon, and De Wilde, 1998). There are now at least eight patients with category-specific deficits for living things who have been tested with property judgment tasks in which the difficulty levels of the visual and functional/associative attribute judgments have been equated. In all cases, no difference was observed between visual and functional/associative attribute conditions. A summary of the performance of some of these cases is shown in table 72.1.

Equally problematic for the SFT is the recent observation that patients with disproportionate difficulties in processing visual attributes of objects do not show greater impairment for the category of living things (Coltheart et al., 1998; Lambon-Ralph et al., 1998). For example, in a word-to-definition matching task, patient IW (Lambon-Ralph et al., 1998) was far worse at matching definitions that stressed perceptual attributes than those that stressed functional/associative attributes (46% versus 79%, respectively). However, in various naming tasks involving several hundred items all together, she performed better or equally well with the category of living than the category of nonliving things (42% versus 33% correct, respectively).

None of the major predictions derived from the SFT has received empirical confirmation: (1) The pattern of attested semantic category-specific deficits does not conform with the expectation that certain semantic categories should always be impaired (or spared) together; (2) category-specific deficits for living things are not associated with disproportionate impairment for visual attributes of objects; and (3) selective deficit for visual

attributes is not associated with disproportionate impairment for the category of living things. And there is reason to be skeptical about the truth of this theory's assumption about the relative importance of visual and functional/associative properties in distinguishing between living and nonliving things, respectively. The empirical justification for this claim was provided by Farah and McClelland (1991), who had subjects count the number of visual and functional attributes in dictionary definitions of living things and nonliving things. They found that the ratio of visual to functional/associative attributes is much larger for living than nonliving things. However, the instructions given to subjects had the effect of excluding from the count of functional/associative properties of living things such attributes as "carnivore" and "lives in desert regions." When instructions allow subjects to count such attributes, the ratios of visual to functional/associative properties for living and nonliving things are roughly equal (Caramazza and Shelton, 1998).

Computational modeling Computational modeling does not provide empirical support for cognitive or neural theories. However, it can provide existence proofs of the viability of complex theories. Farah and McClelland developed a computational model of semantic memory consisting of separate visual and functional/associative subsystems. Their model implemented the assumptions made by the SFT—the ratio of visual to functional/associative attributes was larger for living than nonliving things. When the visual component was damaged selectively, the system performed more poorly in "naming" living than nonliving things. The reverse dissociation was obtained when the functional/associative component was damaged selectively. Furthermore, it was found that damage to one of the modality-specific semantic subsystems (e.g., the visual semantic component) resulted in greater impairment for the properties

associated with that modality (visual properties) but also with some impairment for the properties associated with the spared semantic subsystem (functional/associative properties). Thus, this model provides an existence proof that category-like effects can be obtained even when there is no underlying categorical organization in the system. However, this demonstration merely establishes that if information is segregated in such a way that one part is more important for one category than for another, then it is possible to damage part of the information so as to produce disproportionate consequences for one category over another. The value of this demonstration specifically for the SFT (as opposed to any theory that assumes some type of correlation between property types and categories) is that damage to the visual component resulted in greater impairment for the visual attributes of living than nonliving things. But, as we have seen, there is no reliable evidence that category-specific deficits for living things are associated with disproportionate impairment for the visual attributes of objects.

Neuroimaging results Martin (1998) has interpreted the results of several neuroimaging studies as providing support for a modality-based organization of conceptual knowledge. Two studies in particular are relevant to his argument. In one PET study, Martin and his collaborators (Martin et al., 1995) asked subjects to retrieve either the color (e.g., red) or an action (e.g., pull) typically associated with an object (e.g., wagon). They found that retrieving the color of objects led to the activation of the inferior region of the temporal lobe whereas retrieving actions associated with objects led to activation of a more superior region of the temporal lobe. Intriguingly, these areas are close to areas known to mediate color and motor perception, respectively. In another PET study, Martin and associates (Martin et al., 1996) asked subjects to name pictures of animals and tools. They found that naming tools (relative to animals) activated a region of the left temporal lobe similar to that activated by action naming in their earlier experiment. They also found that tool naming activated a region of the left premotor cortex that corresponds roughly to an area that is activated during imaging of actions (Decety et al., 1994). Animal naming (relative to tools) activated the inner surface of occipital cortex, bilaterally (see also Perani et al., 1995).

The results of these studies suggest that brain areas closely associated with modality-specific processing (vision and action) are differentially involved in processing animate objects and artifacts. These are very interesting results. However, they do not require us to adopt a modality-specific theory of *semantics*. The results might only be telling us something about processing differences at

the level of visual structural descriptions of objects and the imagery of action. In support of the latter interpretation of the PET results obtained by Martin and collaborators, we note that patients with category-specific semantic deficits for living things tend to have lesions involving temporolimbic structures, inferotemporal areas, or posterior frontal/parietal areas and not the occipital cortex. And there is no reliable evidence that category-specific semantic deficits result from damage to modality-specific semantic subsystems. Further support for this interpretation is provided by the results of a study by Tranel, Damasio, and Damasio (1997), who found that patients with right occipital lesions have disproportionate difficulties recognizing pictured animals but are otherwise supposedly unimpaired at the conceptual level. In other words, the occipital lobes may be important in processing the visual structural representations of objects and not their conceptual content.

The correlated-structure principle

The SFT is not the only reductionist account that can be given for the existence of semantic category-specific deficits. In other words, we do not have to assume a modality-based organization of conceptual knowledge in the brain for category-specific effects to “emerge” from a noncategorically organized conceptual system. For example, given certain assumptions about the structure of concepts (see S. Gelman and Coley, 1990; Keil, 1989; Rosch, 1973, 1975) and given the assumption that highly correlated properties are represented near each other in the brain, we can account for the existence of category-specific deficits. The following assumptions are sufficient: (1) The members of natural-kind categories (e.g., animals, plant life) share many more properties in common than do the members of artifact categories; (2) attributes are not distributed uniformly across objects but vary considerably in their likelihood of co-occurrence; (3) the attributes of natural-kind objects are more highly intercorrelated than the attributes of artifacts, but the latter can also be highly intercorrelated; and (4) highly correlated properties tend to cluster together in the brain. Given these assumptions, the semantic properties of natural-kind objects are highly likely to be found near each other and hence are more likely to be damaged together.

The Organized Unitary Content Hypothesis (OUCH) is one instantiation of these principles (Caramazza et al., 1990), but there are various other possibilities (e.g., see Devlin et al., 1998; Durrant-Peatfield, Moss, and Tyler, 1998). The core assumption in OUCH is that conceptual space is “lumpy.” That is, it is assumed that semantic properties are not distributed uniformly across catego-

ries, but tend to cluster together, independently of their modality. For example, objects that are capable of a particular type of motion are likely to be made of certain kinds of stuff (substance, texture, color), to have particular odors, to have particular shapes, and to be found in particular types of environments (think of chicken or elephant). Similarly, objects that are shaped like a hammer and are not capable of biological motions tend to be made of certain kinds of stuff (metals, plastics, wood), to have particular odors, and to be found in particular types of environments. In other words, the lumpiness of semantic space reflects in part the distinction between natural kinds and artifacts. Brain damage that affects one of the lumpy regions of semantic space would result in category-like effects.

OUCH (and similar models) can account for the fact that living and nonliving things can be damaged independently of each other. It also naturally accounts for the fact that category-specific deficits are not associated with selective impairment to a modality-defined type of knowledge. Thus, the model is generally consistent with the major neuropsychological observations on record. However, it is silent on whether finer-grained dissociations are possible and what form they might take. To be sure, it is not unreasonable to assume that animals should dissociate from fruits and vegetables because the two classes of objects share few attributes. But such expectations are based on simple intuition and not on an articulated set of claims about the structure of semantic space. This does not mean that it is impossible to make progress in specifying such structure; but until such steps are taken, it is not possible to subject the theory to serious empirical test. Nonetheless, the correlated-structure principle for the organization of conceptual knowledge in the brain remains a viable candidate, albeit without direct empirical support at this time.

The domain-specific principle

As already noted, the existence of category-specific deficits would seem to provide *prima facie* evidence for some type of categorical organization of conceptual knowledge. But what might the categories of such a categorical organization be? Are “vehicles” and “animals” semantic categories for the purposes of this theory? And what about “European cars,” “airplanes,” “aquatic animals,” “furniture,” and “objects typically found in a house”? Is any one of these the right sort of category for the organization of conceptual knowledge in the brain? A theory that would advocate a categorical organization of conceptual knowledge would have to articulate the nature of the categories and provide independent motivation for the proposed set of categories.

Caramazza and Shelton (1998) have argued that evolutionary pressures resulted in specialized neural mechanisms for perceptually *and* conceptually distinguishing specific kinds of objects, leading to the categorical organization of knowledge in the brain (e.g., R. Gelman, 1990; Premack, 1990). The range of categories that can be subsumed under this principle is very narrow—it is restricted to categories of objects whose rapid and accurate classification would have led to survival and reproductive advantages. Plausible candidates are the categories of conspecifics, animals, and plant life (and perhaps artifacts). The fitness value of specific adaptations for recognizing and responding to these types of objects would seem to be uncontroversial: Animals are potential predators and a source of food, plants are a source of food and medication, and conspecifics are a source of nurturance and protection. Thus, the domain-specific assumption provides a principled motivation for restricting the categories of category-specific deficits (or selective sparing) to the categories of conspecifics, animals, and plant life (fruits and vegetables). In this framework, cases of category-specific deficit for nonliving things are actually cases of selective sparing of the evolutionarily defined categories of conspecifics, animals, and plant life (but see Hauser, 1997, for the possibility that artifacts should be accorded a comparably evolutionarily important status).

What evidence can we adduce in support of this claim? The evidence is indirect. It consists of the patterns of categories involved in category-specific semantic deficits. Earlier, we noted that there are finer-grained, category-specific deficits than the simple dichotomy living/nonliving things. Various dissociations have been reported. A summary of the dissociations involving animals, fruits and vegetables, and artifacts is shown in table 72.2. The most clearly documented cases concern the category of animals. Patient EW, whose performance was described earlier, is selectively impaired in processing animals. This pattern of performance contrasts with that of another patient, JJ (Hillis and Caramazza, 1991), who was shown to have a severe impairment in processing all categories tested but animals. Another category that can be damaged selectively is that of fruits and vegetables (plant life?). There are reports of selective impairment of this category (Farah and Wallace, 1992; Hart, Berndt, and Caramazza, 1985) and of its selective impairment relative to the category of animals (Hillis and Caramazza, 1991). These cases of disproportionate impairment of fruits and vegetables contrast with cases of selective sparing relative to the category of animals (Caramazza and Shelton, 1998; Hart and Gordon, 1992). Finally, there are various reports of selective deficit (e.g., Dennis, 1976; Goodglass and

TABLE 72.2
Selected cases of category-specific deficits

Budin, 1988) or sparing (e.g., Goodglass and Wingfield, 1993; Shelton, Fouch, and Caramazza, 1998) of body parts, which might reflect the autonomy of conceptual knowledge of conspecifics.

The pattern of category-specific deficits reviewed here conforms well with expectations derived from the domain-specific hypothesis. The categories for which there is reliable evidence of selective deficit (or sparing) are precisely those that might be considered to be evolutionarily important—those classes of objects for which it can plausibly be argued that their rapid and accurate recognition would have fitness value. The animate/inanimate distinction certainly satisfies this criterion. And there is converging evidence from the developmental literature that this distinction is especially salient in very young infants. There are compelling results showing that very young infants can easily distinguish between biological and nonbiological motion and can distinguish self-initiated from caused motion (Bertenthal, 1993; Spelke, Phillips, and Woodward, 1995). Furthermore, there is evidence that young infants can easily distinguish between animals and visually similar artifacts, indicating that they can make the global differentiation animate/inanimate before they can identify individual animals or artifacts (Mandler, 1992).

Conclusion

Neuropsychological and neuroimaging results are beginning to provide the foundations on which to base empirically testable proposals about the organization of conceptual knowledge in the brain. The available results do not support the view that conceptual knowledge is organized into modality-specific semantic subsystems. The major evidence against this view is provided by the patterns of category-specific semantic deficits. These deficits can be quite discrete, involving fairly narrow se-

mantic categories such as animals, body parts, or fruits and vegetables. Furthermore, patients with category-specific deficits involving these categories are not also disproportionately impaired for the visual attributes of objects, contrary to a core prediction of modality-specific semantic theories. These results are consistent with unitary, modality-neutral semantic accounts. And they encourage the view that the conceptual system consists of domain-specific structures reflecting evolutionary adaptations.

NOTES

1. I do not discuss number concepts here. However, it is not implausible that number concepts are organized as a separate domain of knowledge (see Dehaene, 1997; Hauser, 1997).
2. Note the distinction between “semantic category-specific deficits” and “category-specific semantic deficits.” The former, the semantic category-specific deficits, refers to deficits that are restricted to a semantic category (as opposed to, say, a grammatical category) but do not necessarily involve damage to the semantic system (but they could, of course). That is, they could simply involve deficits restricted to lexical access or to object recognition for a particular semantic category. Because in this chapter I only consider deficits involving semantic categories, I drop the modifier “semantic,” accepting as understood the fact that “category-specific” deficits refers to deficits restricted to one or another semantic category. By contrast, “category-specific semantic” deficit refers to a deficit that is restricted to a semantic category *and* the damage is at the level of the semantic system.
3. By claiming that EW’s performance is typical of certain patients with category-specific deficits, I do not mean to imply that the patients have the same neurological or cognitive

deficit. I mean only that these patients can all be shown to have at least a semantic deficit in addition to whatever other deficits their particular form of brain damage might have produced. Patient classification for the purpose of cognitive research remains controversial (see Caramazza, 1986).

4. Caution should be exercised in interpreting the early cases of category-specific deficit. Funnell and Sheridan (1992) and Stewart, Parkin, and Hunkin (1992) have shown that semantic categories can vary considerably in terms of the familiarity and visual complexity of their members. And since these factors are important determinants of recognition/naming performance, the interpretation of performance differences across categories is legitimate only if the contribution of these factors is taken into consideration. Unfortunately, not all studies have systematically controlled these factors. Consequently, we cannot be sure that all putative cases of category-specific deficit are "true" cases of selective deficit of a semantic category.

73 Decision Making and the Somatic Marker Hypothesis

DANIEL TRANEL, ANTOINE BECHARA, AND ANTONIO R. DAMASIO

ABSTRACT How do we make decisions, simple or complicated? Which neural structures are important for decision making? Why do we sometimes make decisions that are favorable to us and sometimes decide against our best interests? Why do some individuals have a proclivity for bad decision making? These are just a few of the pressing questions regarding decision making—questions that are finally being asked within the compass of cognitive neuroscience.

We have been investigating the neural basis of decision making by using a theoretical framework known as the *somatic marker hypothesis*. The framework proposes that decision making is dependent on signals from bioregulatory responses—those responses that are aimed at maintaining homeostasis and ensuring survival. The highest level of such responses includes emotions and feelings. We have studied both normal individuals and neurological patients whose decision making is profoundly impaired following damage to various sectors of the central nervous system (including the ventromedial prefrontal region, the right somatosensory and insular cortices, and the amygdala) and to the peripheral nervous system. Neuropsychological and psychophysiological experiments in these patients have yielded intriguing new insights into the neural architectures required for decision making. A surprising conclusion from our work is that too little emotion has profoundly deleterious effects on decision making; in fact, too little emotion may be just as bad for decision making as excessive emotion has long been considered to be. Our work indicates that individuals utilize bioregulatory responses, including emotions and feelings, to guide decision making in several important ways, both consciously and nonconsciously.

Emotion and the somatic marker hypothesis

BACKGROUND Throughout the history of neuropsychology, the psychological capacities associated with the prefrontal region of the brain have remained enigmatic and elusive. However, the special significance of this region has long been linked to the idea that it provides the neural substrate for a collection of higher-order capacities such as planning, reasoning, self-awareness, empathy, emotional modulation, and especially, decision making (cf. Benton, 1991). Also, the portion of the pre-

frontal region formed by the orbital and lower mesial sectors (“ventromedial”) has been considered by some to be the neural basis for “personality.” Over the past century, a number of case studies supported this idea, as investigators called attention to the oftentimes bizarre development of abnormal social behavior following prefrontal brain injury (e.g., Damasio, 1979; Damasio and Anderson, 1993; H. Demasio et al., 1994; Eslinger and Damasio, 1985; Stuss and Benson, 1986). The affected patients had a number of features in common: inability to organize future activity and hold gainful employment, diminished capacity to respond to punishment, and tendencies to present an unrealistically favorable view of themselves and to display inappropriate emotional reactions. Making this profile all the more puzzling was the fact that most of these patients retained normal intelligence, language, memory, and perception.

This personality profile bears some striking similarities to that characterized in clinical psychology and psychiatry as *psychopathic* (or *sociopathic*) (American Psychiatric Association, 1994). In fact, we have designated this condition as “acquired sociopathy,” thereby emphasizing the fact that prefrontal injured patients have many personality manifestations that are highly reminiscent of those associated with sociopathy (Damasio, Tranel, and Damasio, 1990, 1991; Tranel, 1994). The qualifier “acquired” signifies that in the brain-damaged patients, the condition follows the onset of brain injury, and occurs in persons whose personalities and social conduct were previously normal. Patients with acquired sociopathy are inclined to engage in decisions and behaviors that have repeated negative consequences for their well-being. The patients are usually not destructive and harmful to others, a feature that tends to distinguish the acquired form of the disorder from the standard developmental form. However, they repeatedly select courses of action that are not in their best interests in the long run. They act as though they have lost the ability to ponder different courses of action and then select the one that promises the best blend of short- and long-term benefit. They have difficulty planning and organizing their lives: They cannot

DANIEL TRANEL, ANTOINE BECHARA, and ANTONIO R. DAMASIO Department of Neurology, Division of Behavioral Neurology and Cognitive Neuroscience, University of Iowa College of Medicine, Iowa City, Iowa

plan their work and they make poor decisions about friends, business associates, and assorted activities. In short, the choices these patients make are neither personally advantageous nor socially adequate. And of particular importance, the choices are very different from the kinds of choices the patients were capable of before the onset of their brain injury.

THE SOMATIC MARKER HYPOTHESIS One observation was key to the development of the somatic marker hypothesis: Although patients with ventromedial prefrontal damage were capable of performing normally on nearly every neuropsychological test they were asked to take, and obviously had preserved conventional intellectual functions, their ability to express emotion and experience feeling relative to complex personal and social situations, for example, as in the expression and experience of embarrassment, was compromised. Given that primary disturbances of intellect, memory, language, attention, or working memory could not explain the bizarre changes in social conduct and decision making typical of these patients, we proposed that deficits in bio-regulatory responses might provide a plausible explanation (Damasio, Tranel, and Damasio, 1990, 1991; Damasio, 1994, 1995a,b, 1996). In brief, we can describe the *somatic marker hypothesis* as follows:

1. Certain structures in prefrontal cortex are required in order to learn associations between various classes of complex (higher-order) stimuli and various internal states of the organism (such as emotions) usually experienced in conjunction with those classes of stimuli. These internal states are represented in the brain as transient changes in patterns of activity in somatosensory maps of a large collection of structures, from the brain stem and hypothalamus to the cerebral cortex. We refer to these states as “somatic” (meaning all components of the soma, including the musculoskeletal, the visceral, and the internal milieu).

2. When a situation from a particular class of complex stimuli recurs in one’s ongoing experience, systems in the ventromedial prefrontal region—those that previously acquired the association between that class of stimuli and a certain class of somatic states—trigger the reactivation of the somatosensory pattern depicting the appropriate somatic state. This can be achieved by two routes—a *body loop* or an *as-if-body loop*. In the body loop, the soma actually changes in response to the activation, and signals of those changes are relayed back to somatosensory maps; in the as-if-body loop, the reactivation signals are relayed directly to somatosensory maps, bypassing the body and prompting the appropriate pattern of activation in the somatosensory structures. Moreover,

each of these mechanisms—the body loop and the as-if-body loop—may operate either overtly (consciously) or covertly (nonconsciously).

3. With regard to reasoning and decision making, the reactivation of the somatosensory pattern appropriate to a given situation, concurrent with evocation of pertinent factual knowledge, operates to constrain the reasoning and decision-making space via a qualification mechanism. That is, when the somatosensory pattern image is juxtaposed both to the images prompting the somatic state and those depicting potential outcomes, the somatosensory pattern *marks* outcomes as good or bad. When it operates covertly, the somatic marker constitutes a nonconscious biasing signal that facilitates appetitive or avoidance behavior. When it operates overtly, the somatic marker process serves as an incentive or deterrent.

4. Patterns of somatosensory activity can also facilitate attention and working memory, thereby influencing the decision-making process indirectly.

5. The mechanisms described in steps 3 and 4 facilitate logical reasoning.

A NEURAL NETWORK FOR SOMATIC MARKERS We have proposed that the ventromedial prefrontal cortices hold records of temporal conjunctions of activity in various neural units (e.g., sensory cortices, limbic structures), arriving from both external and internal stimuli. They do so in the form of convergence zones (Damasio, 1989a,b). The records hold signals from simultaneously active neural regions, which, as a set, define particular situations. A key output of ventromedial convergence zones is to autonomic effectors, as follows: When aspects of a particular exteroceptive-interoceptive conjunction are reprocessed (nonconsciously or consciously), activation is signaled to ventromedial prefrontal cortices, which in turn activate somatic effectors in structures such as the amygdala, hypothalamus, and brainstem nuclei. In essence, there is an attempt to reconstruct the kind of somatic state that belonged to the original conjunction as learned and modified by experience. The reconstituted somatic state is then signaled to cortical and subcortical somatosensory structures, whence it triggers either a covert process modifying appetitive/aversive behavior or a conscious perception in the form of a *feeling*.

Anatomically, the ventromedial prefrontal cortices are well suited for their role as dispositional convergence zones.¹ They receive projections from all sensory modalities, directly or indirectly (Chavis and Pandya, 1976; Jones and Powell, 1970; Pandya and Kuypers, 1969; Potter and Nauta, 1979). They project to central autonomic effectors (Nauta, 1971), which have, in turn, a physiological influence on visceral control (Hall, Livingston, and Bloor, 1977). They also have extensive two-

way connections with the amygdala and hippocampus (Amaral and Price, 1984; Goldman-Rakic, Selemon, and Schwartz, 1984; Porrino, Crane, and Goldman-Rakic, 1981; Van Hoesen, Pandya, and Butters, 1972, 1975). In short, the ventromedial prefrontal cortices receive signals regarding multiple-site representations of scenarios of complex situations from early sensory cortices, and they also receive signals from somatosensory cortices and bioregulatory structures. They can originate signals to bioregulatory structures including the amygdala, hypothalamus, and brainstem nuclei.

To summarize, the anatomical systems network required for somatic markers includes the following: (1) Ventromedial prefrontal cortices containing convergence zones that record associations between the dispositions that represent (a) classes of complex situations and (b) somatic states prepotently associated with such complex situations; (2) central autonomic effectors, including the amygdala, capable of activating somatic responses in the viscera, vascular bed, endocrine system, and nonspecific neurotransmitter systems; (3) somatosensory and insular cortices and their associated two-way projections. Later in this chapter, we describe a systematic investigation of many of the components of the somatic marker neural network.

Consider, for example, a complex social scenario requiring certain decisions and courses of action, say, a tense faculty meeting concerning promotions and work assignments. Dispositions are activated in higher-order association cortices, leading to the recall of pertinent facts and related knowledge. The contingent ventromedial prefrontal linkages are activated concurrently, leading to activation of the emotional disposition apparatus—the amygdala, ventral striatum, cingulate, insular cortex, and so forth. The net result is a reconstruction of a previously learned factual–emotional set. In other words, the somatosensory pattern evoked by a particular situation is co-displayed with factual knowledge pertinent to the situation. With respect to decision making, the key idea is that the somatosensory pattern operates to constrain the process of reasoning over multiple options and multiple future outcomes. Images of future scenarios are marked, and thus “qualified” or “judged,” by the juxtaposed images of the somatic state. In a complex decision-making space, this process greatly facilitates the operation of logical reasoning. Somatic markers allow certain option–outcome pairs to be rapidly endorsed or rejected, rendering the decision-making space more manageable for a subsequent cost–benefit analysis based on overt logical reasoning. In situations with a high degree of uncertainty as to the future and/or which course of action is optimal, the constraints imposed by somatic markers allow individuals to decide efficiently within

reasonable time intervals. This would apply to many complex social situations, and to the on-line navigation required therein.

In the absence of somatic markers, response options and outcomes become more or less equalized. Subjects may then resort to a strategy of deciding on an option based on extremely slow and laborious logic operations over many potential alternatives, themselves lacking somatic markers, and hence fail to take affectively salient previous experience into account. As a consequence, decision making may fail to be timely, accurate, and propitious. Another possible consequence of missing somatic markers is that decision making may become random or impulsive. Such manifestations, as it seems, are precisely what one sees in the real-world behavior of patients with damage to ventromedial prefrontal cortices.

WHY IS EMOTION IMPORTANT? Before turning to a description of recent work and to the testing of various aspects of the somatic marker hypothesis, let us briefly comment on why we consider emotion a crucial ingredient in the process of reasoning and decision making. Situations involving personal and social matters are typically, and powerfully, associated with reward and punishment, with pleasure and pain—in short, with the regulation of homeostatic states as expressed by emotions and feelings. So, assuming the brain owns a mechanism for selecting good from bad responses in social situations, we suggest that this mechanism was co-opted for behavioral guidance, even though, strictly speaking, it falls outside the purview of social cognition. Whether or not they are perceived consciously in the form of feelings, somatic markers provide the “go,” “stop,” and “turn” signals needed for much decision making and planning, even in regard to highly abstract topics.

Testing the somatic marker hypothesis

SOMATIC RESPONSES TO EMOTIONALLY CHARGED STIMULI The somatic marker hypothesis predicts that patients with ventromedial prefrontal dysfunction would fail to generate somatic responses to emotionally charged stimuli. That is, we contend that the ventromedial prefrontal region is pivotal to the reactivation of somatic states normally associated with powerful emotional stimuli in the course of an individual’s learning experience; hence, damage to this region should attenuate or abolish such somatic responses. We tested this prediction in the following experiments (Damasio, Tranel, and Damasio, 1990, 1991; Tranel, 1994).

Three groups of subjects were tested: (1) ventromedial prefrontal, comprising five subjects with bilateral

FIGURE 73.1 Skin conductance response (SCR) magnitudes to orienting stimuli, neutral pictures, and emotionally charged pictures in normal controls, brain-damaged controls, and ventromedial prefrontal subjects. There were no significant differences between the groups in the SCR magnitude for the orienting stimuli. In the ventromedial prefrontal group, the

SCR magnitude for the emotionally charged pictures was severely abnormal. Statistically, it is (1) not different from this group's SCR magnitude for the neutral pictures and (2) significantly lower than the SCRs produced by the normal and brain-damaged controls to the emotionally charged pictures.

ventromedial prefrontal damage and acquired impairments in social conduct and decision making; (2) brain-damaged controls, comprising six subjects with lesions outside the ventromedial prefrontal sector and lacking acquired defects in decision making; (3) normal controls, comprising five individuals having no history of neurological or psychiatric disease. The three groups were of comparable age and education. The subjects were shown two types of visual stimuli: *targets*—pictures of emotionally charged stimuli such as mutilations and nudes; *nontargets*—pictures of emotionally neutral stimuli such as farm scenes and abstract patterns. The dependent measure was the skin conductance response (SCR), a highly sensitive index of autonomic responsivity, especially in regard to emotional stimuli (see Tranel, in press, for a review).

Before showing subjects the target and nontarget pictures, we determined that they were all capable of gener-

ating SCRs to basic physical stimuli (e.g., a loud noise or deep breath), thereby ruling out the possibility that unresponsiveness to the pictures could be attributed to a general, nonspecific lack of autonomic response. For the experiment proper, we compared the three groups in terms of their average SCRs to the target versus nontarget pictures. Both the normal and brain-damaged control groups displayed large-amplitude SCRs to the targets, and little or no response to the nontargets (figure 73.1). The ventromedial prefrontal subjects, by contrast, generated almost no response to the targets, and completely failed to show the standard target–nontarget SCR difference, despite the fact that their ability to generate SCRs to basic physical stimuli was intact.

The findings from these experiments are consistent with our prediction from the somatic marker hypothesis, and we have interpreted them as evidence that patients

with bilateral ventromedial prefrontal damage have lost the ability to generate normal somatic responses to emotionally charged stimuli. We believe, furthermore, that this defect is a key component of the explanation as to why the real-world social behavior of these patients is so impaired.

THE GAMBLING TASK We have also approached the testing of the somatic marker hypothesis by developing a card game (the Gambling Task) in which the goal is to maximize profit on a loan of play money—a game in which response selection is guided by various schedules of immediate reward and delayed punishment (Bechara et al., 1994). The motivation for developing this task came from the well-replicated finding that many patients with prefrontal damage do not demonstrate impairments on conventional neuropsychological procedures, even quintessential “executive function” or “frontal lobe” tasks such as the Wisconsin Card Sorting Test, the Trail-Making Test, and the Tower of Hanoi (see Tranel, Anderson, and Benton, 1994, for review). The Gambling Task provides a closer analog to real-world decision making, inasmuch as it makes unpredictable rewards and punishments a more explicit aspect of the situation, and requires subjects to forgo short-term benefit for long-term gain. Patients with bilateral ventromedial prefrontal lobe lesions show a reliable pattern of disadvantageous responding on the Gambling Task, even when they are retested again and again over various intervals of time (Bechara et al., 1994). The principal findings are summarized below.

In the Gambling Task, subjects sit in front of four decks of cards equal in appearance and size, and are given a \$2000 loan of money (facsimile U.S. bills). The subjects are told that the game requires a long series of card selections, one card at a time, from any of the four decks, until they are told to stop. After turning each card, the subjects receive some money (the amount is announced only after the turning, and it varies from deck to deck). After turning certain of the cards, however, the subjects are both given money and asked to pay a penalty (again, the amount is announced only after the card is turned, and it varies from deck to deck and from position to position within a given deck, according to a schedule unknown to the subjects). The subjects are told that the goal of the task is to maximize their profit, and that they are free to switch from any deck to another, at any time, and as often as they wish. Subjects are not told ahead of time how many card selections will be made in all (the task is stopped after 100 selections).

Turning any card from deck A or deck B yields \$100; turning any card from deck C or deck D yields \$50. However, the ultimate future yields of the decks vary,

because the penalty amounts are higher in the high-paying decks (A and B), and lower in the low-paying decks (C and D). In fact, the task is rigged so it is better to select from decks C and D over the long haul. Decks A and B are disadvantageous because they cost the subject in the long run; decks C and D are advantageous because they result in an overall gain to the subject in the long run.

In our study (Bechara et al., 1994), we investigated the performances of three groups of subjects on the Gambling Task: (1) ventromedial prefrontal, comprising six subjects with bilateral ventromedial prefrontal lesions and abnormal real-world decision making; (2) brain-damaged controls, comprising six subjects with lesions outside the ventromedial prefrontal region and lacking decision-making deficits; and (3) normal controls, comprising 44 subjects free of neurological or psychiatric disease. The three groups were age- and education-matched. To determine what would happen to performance when the task was repeated over time, we retested the ventromedial prefrontal subjects and five normal controls at follow-up intervals of 1 and 6 months.

To evaluate performance on the Gambling Task, we subdivided the 100 card selections into 5 discrete blocks of 20 each; and for each block, we calculated the number of selections for decks A and B (disadvantageous) and the number of selections for decks C and D (advantageous). The results are presented graphically in figure 73.2, broken down as a function of group, block, and deck type. As the task progressed, normal and brain-damaged controls gradually shifted their selections toward the good decks (C and D), and away from the bad decks (A and B). By the last two blocks (trials 61–100), in fact, the subjects were choosing almost exclusively from the good decks. In sharp contrast, ventromedial prefrontal subjects failed to demonstrate this shift in behavior. In all but one trial block, they selected more cards from the bad decks, and fewer from the good decks; on blocks 4 and 5, they reliably selected more frequently from the disadvantageous decks, which is a strikingly different pattern than that produced by the control subjects. A 3 (group) \times 2 (deck) \times 5 (block) ANOVA on these data showed significant interactions between deck and group ($F(2,53) = 20.78, p < .0001$) and between deck and block ($F(4,212) = 12.58, p < .0001$); also, the three-way interaction was significant ($F(8,212) = 2.69, p < .01$). Together, these outcomes reflect the fact that as the task progressed, both control groups showed a strong shift away from the bad decks and toward the good decks, whereas the ventromedial prefrontal group failed to shift their behavior toward more advantageous responding, and in fact, persisted reliably with the bad decks during the last 40 trials of the session.

FIGURE 73.2 Card selections on the Gambling Task as a function of group (normal control, brain-damaged control, and ventromedial prefrontal), deck type (disadvantageous versus advantageous), and trial block. The two control groups gradually shifted their response selections toward the advantageous

decks, and this tendency became stronger as the game went on. The ventromedial prefrontal subjects did not make a reliable shift, and continued to opt for the disadvantageous decks even during the latter stages of the game, when controls had almost completely abandoned choosing from the bad decks.

A follow-up study showed that the performances of the ventromedial prefrontal subjects did not improve over time; they performed in a similar defective manner (disadvantageous responding) at both 1-month and 6-month follow-up epochs. The performances of the control subjects did improve over time, as the subjects retained their learning from the first session, and avoided the bad decks even earlier in the game than they had in the original go-round.

ANTICIPATORY PSYCHOPHYSIOLOGICAL RESPONSES
Our next experiment in this series of studies involved adding a psychophysiological dependent variable to the Gambling Task paradigm, in order to assess somatic state activation during the task (Bechara et al., 1996b). Specifically, we measured skin conductance responses during the task, as follows.

We studied two groups of subjects: (1) ventromedial prefrontal, comprising seven subjects with bilateral ventromedial prefrontal lesions and real-world decision-making deficits, and (2) normal controls, comprising twelve neurologically and psychiatrically healthy individuals who were age- and education-matched to the ventromedial subjects.

The psychophysiological measure was skin conductance responding (SCR), which was recorded while subjects performed the Gambling Task. Equipment,

recording, and scoring procedures were as described in some of our other work (e.g., Tranel and Damasio, 1989, 1994). Skin conductance electrodes were attached, then the subject was seated in front of a table on which the four decks of cards were placed. The decks were in close proximity to the subject, to minimize the motor response demand required for the subject to reach out and select a card. One experimenter sat across from the subject and administered the task. The subject was instructed to select a card from one of the decks, whenever a second experimenter (who was monitoring the polygraph record) gave the signal to "go." The subject was not allowed to respond again until the signal was again delivered. This format allowed us to identify precisely each SCR generated in association with a specific card from a specific deck. Approximately 15 seconds elapsed between card turns.

Three types of SCRs generated during the task were defined: (1) *reward* SCRs, defined as the SCRs generated after the subject had turned cards for which there was a reward and no penalty; (2) *punishment* SCRs, defined as the SCRs generated after the subject had turned cards for which there was a reward followed immediately by a penalty; and (3) *anticipatory* SCRs, defined as the SCRs generated immediately *prior* to the point at which the subject turned a card from any given deck, i.e., during the time period the subject was pondering from which deck to choose. The time window for the onset of reward and

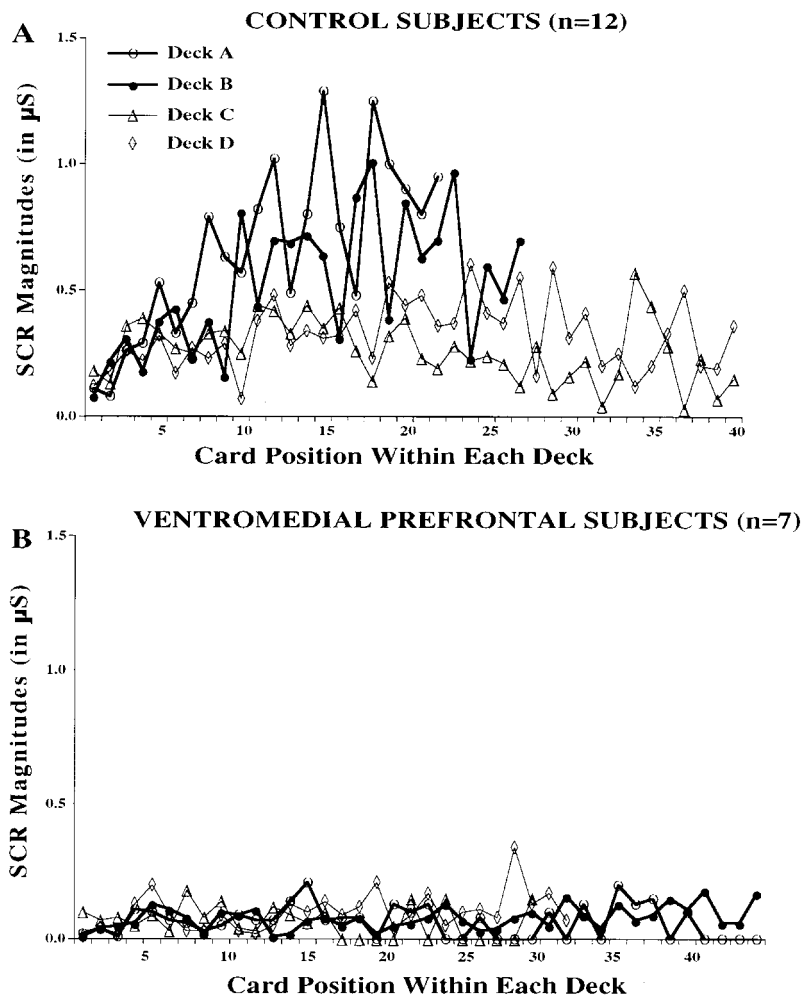

FIGURE 73.3 Anticipatory SCR magnitudes as a function of group, deck, and card position within each deck: (A) control subjects; (B) ventromedial prefrontal subjects. While pondering from which deck to choose, control subjects gradually be-

gan generating high-amplitude SCRs to the disadvantageous decks (A and B), but not to the advantageous decks (C and D). The ventromedial prefrontal subjects showed no such anticipatory SCRs.

punishment SCRs was within 4 seconds after receipt of feedback information (e.g., “You have won \$500”). SCRs generated during the time between completion of the money exchange and the next card selection were considered anticipatory SCRs.

Both ventromedial prefrontal and control subjects generated SCRs in reaction to reward and punishment.² However, as they became experienced with the task, controls also began to generate SCRs *prior* to the selection of some cards (figure 73.3A). The ventromedial prefrontal subjects entirely failed to generate such anticipatory SCRs (figure 73.3B). A statistical analysis indicated that controls generated anticipatory SCRs in relation to decks A and B (the disadvantageous decks) which were higher than those generated in relation to decks C and D (advantageous decks); no such difference was evident in the ventromedial prefrontal subjects.

Analyses of the reward and punishment SCRs revealed only an effect of the decks (punishment SCRs generated in association with deck B, which has the highest magnitude of punishment, were higher than those for deck A; figure 73.4). There were no statistically significant between-group differences in the reward and punishment SCRs (although controls did tend to produce marginally larger SCRs for most of the decks). Further inspection of the results indicated that the anticipatory SCRs generated by controls (1) developed over time, i.e., the subjects began to respond, and responded more systematically, after selecting several cards from each deck, thereby encountering several instances of reward and punishment; and (2) became more pronounced prior to the selection of cards from the disadvantageous decks (A and B). No such SCRs were evident in the ventromedial prefrontal subjects (figures 73.3 and 73.4).

FIGURE 73.4 Anticipatory, reward, and punishment SCR magnitudes for control subjects and ventromedial prefrontal subjects. The groups did not differ from one another in their reward and punishment SCRs; and as expected, SCRs were largest to the deck with the highest magnitude of punishment (deck B). However, there was a striking group difference for the anticipatory SCRs. Such responses were virtually absent in the ventromedial prefrontal subjects; in the control subjects, there were large-amplitude anticipatory SCRs for the disadvantageous decks (A and B).

In sum, after a number of trials, control subjects began to generate SCRs prior to their card selections, even while they pondered from which deck to choose. Ventromedial prefrontal subjects never showed such anticipatory responses. We have interpreted these results to indicate that the absence of anticipatory SCRs in the ventromedial patients is a physiological correlate for their insensitivity to future outcomes. This interpretation is compatible with the idea that these subjects fail to activate biasing signals which would serve as value markers in the distinction between choices with good or bad future outcomes. We have reasoned further that these signals also participate in the enhancement of attention and working memory relative to representations pertinent to the decision-making process. Further still, as noted in our sketch of the somatic marker hypothesis, we contend that such signals hail from bioregulatory machinery which sustains somatic homeostasis and can be expressed in emotion and feeling.

SOMATIC MARKERS CAN BE COVERT The somatic marker hypothesis holds that somatic markers can operate either covertly or overtly. To begin testing this aspect of the proposal, we explored the notion that the overt reasoning used to decide advantageously in a complex situation is actually *preceded* by a nonconscious biasing step, one whose results would not be available to consciousness and uses neural systems other than those that

support declarative (conscious) knowledge (Bechara et al., 1997a).

In this study, six subjects with ventromedial prefrontal damage and decision-making defects and ten normal controls of comparable age and education performed the Gambling Task. Behavioral (task performance), psychophysiological (SCRs), and self-report measures were obtained in parallel. The self-report data were used to judge whether subjects had developed a conscious notion of how the game worked, on which basis we divided the task into four “knowledge periods.” To do this, we interrupted the task briefly after each subject had made 20 card selections, then asked the subject to respond to the following prompts: (1) “Tell me all you know about what is going on in this game”; and (2) “Tell me how you feel about this game.” The prompts were repeated at 10-card intervals for the remainder of the task.

After sampling from all four decks, and before encountering any punishments, subjects tended to prefer decks A and B, and no anticipatory SCRs were evident. We defined this as the *pre-punishment* period. After encountering some punishments in decks A and B, the normal subjects began to generate anticipatory SCRs to these decks (as described previously in Bechara et al., 1996b). During this period, though, none of the subjects had any notion as to what was happening in the task, as judged from their self-reports. We defined this as the *pre-hunch* period. Roughly halfway through the task (by about card 50), the normal subjects began to express a “hunch” that decks A and B were less favorable and more risky, and they generated anticipatory SCRs when pondering whether to select a card from the A or B decks. We termed this the *hunch* period. The balance of the task we termed the *conceptual* period, during which most of the normal subjects (seven of ten) reported some knowledge that decks A and B were “bad” in the long run and decks C and D were “good.”

When we scored the behavioral data (card selections) and anticipatory SCR data according to the four knowledge periods, a number of intriguing results emerged (figure 73.5). During the pre-hunch period, there was a significant increase in the magnitude of anticipatory SCRs in the normal subjects; i.e., they began to develop anticipatory SCRs *before* they had any clue as to what was happening in the game, and before their behavior changed clearly in favor of the good decks. During the hunch and conceptual periods, the controls exhibited sustained anticipatory SCR activity to the bad decks, but it began to wane for the good decks. The ventromedial prefrontal subjects failed to show the development of anticipatory SCRs; moreover, they continued to choose more frequently from the bad than the good decks throughout

FIGURE 73.5 Psychophysiological (anticipatory SCRs) and behavioral (card selection) data for control subjects ($n = 10$) and ventromedial prefrontal subjects ($n = 6$), as a function of four knowledge periods. Even before they knew anything consciously about how the game worked (pre-hunch period), control subjects began to generate anticipatory SCRs and to shift their selections away from the bad decks. In the controls, anticipatory SCRs, especially to the bad decks, became more pro-

nounced as the game progressed, and the subjects shifted almost exclusively to the good decks. The ventromedial prefrontal subjects never produced anticipatory SCRs, and they also continued to opt more frequently for the bad decks. This pattern occurred even in ventromedial subjects ($n = 3$) who knew how the game worked at conscious level (conceptual period), and were aware some decks were good and some were bad.

the task. Two additional findings were of particular importance (see figure 73.6): (1) The three controls who failed to reach the conceptual period continued to avoid the bad decks, and they generated anticipatory SCRs whenever they did opt for a bad deck. (2) Three of the six ventromedial prefrontal subjects actually reached the conceptual period; i.e., they produced accurate testimony about knowing the advantageous strategy for the game. Nonetheless, they continued to choose disadvantageously, and failed to generate anticipatory SCRs.

These results suggest that the sensory representation of a situation that requires a decision leads to two nonexclusive, interacting chains of events. (1) The sensory representation of a situation, and/or the facts evoked by it, activate neural systems holding nondeclarative dispositional knowledge related to one's previous emotional experience of similar situations. We believe the ventromedial prefrontal cortices are an important part of the structures holding such dispositional knowledge. Their

activation produces consequent activation of autonomic and neurotransmitter nuclei (and of other regions). The ensuing signals, which remain nonconscious, act as covert biases on circuits that support processes of cognitive evaluation and reasoning. (2) The representation of a situation generates (a) overt recall of pertinent facts (e.g., potential response options and probable future outcomes) and (b) application of conscious reasoning strategies to facts and options. The results from our study suggest that in normal individuals, nonconscious biases guide reasoning and decision-making behavior before conscious knowledge does, and without the help of such biases, overt knowledge may be insufficient to ensure advantageous behavior. It is worth noting that studies in social psychology have led to a similar notion—specifically, that individuals can learn and make decisions with information that is not available to conscious awareness (e.g., Lewicki, Hill, and Czerwiska, 1992). We believe that the autonomic responses detected in our experiment (especially those

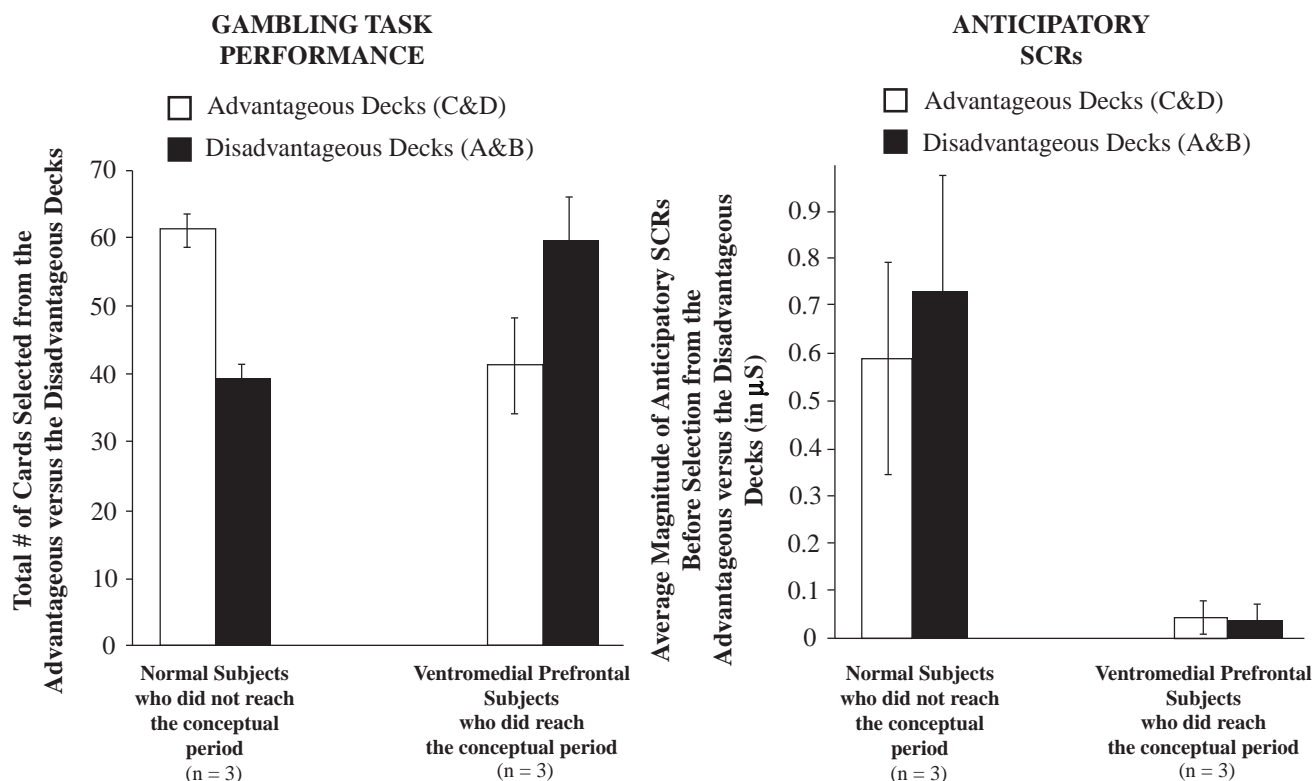

FIGURE 73.6 Gambling Task performance and anticipatory SCRs in 3 normal control subjects who *did not* reach the conceptual period (i.e., never developed an explicit notion of how the game worked) versus 3 ventromedial prefrontal subjects who *did* reach the period (i.e., who knew, and could articulate, the correct strategy for playing the game). Despite their lack of conceptual knowledge, the controls played the game correctly

(i.e., they chose more from the advantageous decks) and continued to generate anticipatory SCRs, especially to the disadvantageous decks. Conversely, conceptual knowledge notwithstanding, the ventromedial prefrontal subjects still played the game incorrectly, and failed to produce anticipatory SCRs.

evident in the pre-hunch period) are evidence for a non-conscious signaling process, which reflects in turn access of records of previous experience shaped by reward, punishment, and apposed emotional states.

FURTHER CHARACTERIZATION OF DECISION-MAKING IMPAIRMENTS IN SUBJECTS WITH VENTROMEDIAL PREFRONTAL DAMAGE

The decision-making impairment is not attributable to working-memory deficits. Our investigations with the Gambling Task raise the question of the extent to which impairments on the task might be attributable to working-memory deficits, rather than to defective decision making per se—this, in spite of the fact that the majority of ventromedial prefrontal subjects are robustly normal in conventional neuropsychological working memory tasks such as digit span backward and trail-making. To test the question further, we designed an experiment in which working-memory tasks adapted from the nonhuman primate literature (the classic paradigms of delayed response and delayed nonmatching to sample, adapted to

use with humans) were used to assess working memory, while the Gambling Task was used to assess decision making (Bechara et al., 1998a).

The working-memory and decision-making tasks were administered to 9 subjects with bilateral ventromedial prefrontal lesions. We also studied 10 subjects with dorsolateral prefrontal lesions (4 right, 6 left), and 21 normal controls. We found a split result in the ventromedial group: 4 subjects were impaired on the decision-making task, but not on the working-memory tasks, while 5 were impaired on both tasks. Detailed lesion analysis indicated that in the first 4 subjects, lesions were situated more anteriorly in the ventromedial region; in the 5 other subjects, lesions extended more posteriorly, probably into the basal forebrain region. The subjects with right-sided dorsolateral prefrontal lesions performed defectively on the working-memory tasks, but not on the decision-making tasks (the left dorsolateral subjects were normal on all tasks).

A double dissociation, cognitively and anatomically, is supported by the results from the anterior ventrome-

dial subjects and the right dorsolateral subjects. This outcome indicates that decision-making impairments produced by ventromedial prefrontal damage are not directly or solely the result of a working-memory impairment. Not surprisingly, however, it probably is true that severely impaired working memory compromises the efficiency of decision making to some extent (the right dorsolateral subjects had relatively lower scores on the Gambling Task, albeit in the normal range). The findings also indicate that the most likely scenario for an isolated impairment in decision making is one involving an anteriorly situated ventromedial prefrontal lesion. With lesions that encompass the posterior sector, which often involve the basal forebrain, the decision-making defect is more likely to be accompanied, and perhaps exacerbated, by working-memory impairments.

Subjects with ventromedial prefrontal lesions are insensitive to future consequences. We have demonstrated that subjects with ventromedial prefrontal lesions utilize a risky strategy when executing the Gambling Task, selecting responses that yield higher short-term rewards but higher long-term punishment. We have interpreted this phenomenon as an indication that such subjects are insensitive to the future consequences of their behavior. But another interpretation is also plausible—that the subjects are simply insensitive to punishment, especially immediate punishment. To test this idea, we designed a variant on the Gambling Task, in which higher magnitudes of immediate punishment were connected to long-term reward, and lower magnitudes of immediate punishment were connected to long-term punishment (Anderson et al., 1996). Specifically, using the basic format of the Gambling Task, we rigged two decks (the good decks) so they would yield higher immediate punishment (monetary losses), but offer occasional large-magnitude rewards (monetary gains); these rewards would more than offset the immediate losses to yield long-term gain. The other two, bad, decks were rigged to yield lower immediate punishment, but also lower rewards; so the long-term outcome was, on balance, negative. We studied 9 ventromedial prefrontal subjects and 10 normal controls. The control subjects learned to select from the good decks as the task progressed; i.e., they opted for higher immediate punishment but higher long-term reward. Most of the ventromedial prefrontal subjects (6 of 9) played the opposite way; i.e., they opted for lower immediate punishment and hence higher long-term loss. All subjects, including controls and ventromedial prefrontals, generated normal SCRs to reward and punishment experiences.

The findings that the ventromedial prefrontal subjects avoided responses associated with lower immediate

punishment, and that they generated normal SCRs to punishment experiences, are inconsistent with the interpretation that the subjects are simply insensitive to punishment. The experiment also showed that the subjects were not lured by occasional large-magnitude rewards (in decks with larger-magnitude immediate punishment), and that they had normal SCRs to reward experiences, suggesting that the subjects are not hypersensitive to reward. Together with findings from the original version of the Gambling Task, this experiment strongly implicates the explanation that the defective strategy of the ventromedial prefrontal subjects is attributable to an overall insensitivity to future consequences, whatever those consequences might be.

THE ROLE OF OTHER NEURAL STRUCTURES IN DECISION MAKING

The amygdala As suggested earlier, the somatic marker hypothesis proposes that the amygdala is another important structure comprising the neural network for somatic markers, although its specific functions may very well differ from those of the ventromedial prefrontal region. There is no question that the amygdala plays an important role in emotion, particularly negative emotion (e.g., fear, anger), as demonstrated repeatedly in recent lesion and functional imaging studies in humans (Adolphs et al., 1994, 1995; Adolphs, Tranel, and Damasio, 1998; Breiter et al., 1996; Brooks et al., 1998; Calder et al., 1996; Morris et al., 1996, 1998; Scott et al., 1997; Whalen et al., 1998. See also *Science*, 1998, Vol. 280, pp. 1005–1008). Following the logic of the somatic marker hypothesis, then, we might also expect the amygdala to play a role in decision making. We tested this idea in the following experiment (Bechara et al., 1996a).

We administered our Gambling Task to 5 subjects with bilateral amygdala damage and to subjects with unilateral left ($n = 3$) or unilateral right ($n = 4$) amygdala damage. [Note: Here, and in the remainder of this chapter, we are referring to the standard version of the task—the one using immediate reward and delayed punishment.] We recorded electrodermal activity (SCRs) throughout the task, using the same procedures described earlier (see Bechara et al., 1996b).

All 5 subjects with bilateral amygdala lesions were impaired in the Gambling Task; i.e., they failed to learn to avoid the bad decks as the game progressed, and played by a strategy that yielded a net long-term loss (figure 73.7). Like the ventromedial prefrontal subjects, the bilateral amygdala subjects failed to generate anticipatory SCRs (despite having normal or near-normal SCRs to basic physical stimuli). Finally, the bilateral amygdala

Bilateral Amygdala Subjects (N=5)

FIGURE 73.7 Gambling Task performance in 5 subjects with bilateral amygdala damage, as a function of deck type and trial block. The subjects never evidenced the normal shift away from the disadvantageous decks and toward the advantageous decks, and in fact, on the last two trial blocks (trials 61–100), demonstrated a small but reliable preference for the bad decks.

subjects also failed to produce SCRs to punishment and reward. The latter finding differs from that obtained in ventromedial prefrontal subjects, who were capable of generating punishment and reward SCRs. We also found that none of the subjects with unilateral amygdala damage was impaired on the task, either in behavioral strategy or in anticipatory and response SCRs. The outcome in bilateral amygdala subjects was replicated and extended in another study (Bechara et al., 1997b).

These findings support the notion that the amygdala is also an important component of the neural network subserving somatic marker activation, albeit in a manner that differs somewhat from that of the ventromedial prefrontal cortices. We have interpreted these results as indicating that the decision-making impairment associated with bilateral amygdala damage is a consequence of a more basic defect in first-order conditioning, i.e., coupling a stimulus configuration (or its concept) with a somatic state triggered by primary reward or punishment (see Damasio, 1995a). Our interpretation derives from a variety of conditioning studies, which have shown that the amygdala is necessary for associating basic perceptual stimuli (e.g., a color or tone) with a somatic state induced by a primary unconditioned stimulus (e.g., an aversive sound, food, electric shock) (Bechara et al., 1995; Davis, 1992; Gaffan, 1992; Kim, Rison, and Fanselow, 1993; LaBar et al., 1995; LeDoux, 1996). As it

pertains to the Gambling Task, this explanation would work as follows. Throughout development, we learn to associate the concepts of “winning” and “losing” money with states of primary reward or punishment (e.g., food, sex, pain), and eventually, those concepts become associated in a more fundamental or primary way with somatic states of their own. When the amygdala is damaged, the concepts of winning and losing can no longer trigger appropriate somatic states. Accordingly, in the Gambling Task, subjects with bilateral amygdala lesions fail to generate SCRs when they win or lose money (i.e., they fail to generate reward and punishment SCRs); also, the subjects fail to activate somatic states when making complex decisions.

On the other hand, we believe the decision-making impairment associated with ventromedial prefrontal damage is a manifestation of a defect in higher-order conditioning, i.e., coupling a strategy or plan of action with a somatic state elicited by the concept of how that course of action may eventually turn out. Conditioning experiments have shown that the ventromedial prefrontal cortices are not required for the acquisition of fear conditioning in nonhuman animals (Morgan and LeDoux, 1995). Similarly, we have shown that in humans, the ventromedial prefrontal cortices (particularly the anterior sector) are not required for conditioning involving a basic perceptual stimulus, say a color or tone, associated with a primary unconditioned stimulus, such as an aversive loud sound (Tranel et al., 1996). This indicates that the ventromedial prefrontal region is not necessary for first-order conditioning, and its damage should not preclude the ability of a primary, basic-level concept to trigger an appropriate somatic state. Accordingly, ventromedial prefrontal subjects are capable of generating SCRs in response to winning or losing money in the Gambling Task. After experiencing punishment in connection with certain response selections, though, the ventromedial prefrontal subjects fail to link this experience with the disadvantageous response strategy; consequently, they fail to generate anticipatory SCRs when pondering their card selections.

Thus, while both the ventromedial prefrontal cortices and the amygdala are important components of the neural network for decision making, their roles are somewhat different. Both structures couple exteroceptive sensory information with interoceptive information concerning somatic states, but these coupling mechanisms involve different types of information. Specifically, the amygdala is necessary for first-order conditioning, whereas the ventromedial prefrontal region is necessary for higher-order conditioning. This interpretation is consistent with the claim that the human prefrontal cortex, particularly its anterior-most aspect, is the most advanced on the evolu-

GAMBLING TASK PERFORMANCE

FIGURE 73.8 Gambling Task performance in 13 normal control subjects, 6 subjects with left somatosensory/insular cortex lesions (LSS/I), and 12 subjects with right somatosensory/insular cortex lesions (RSS/I). The RSS/I subjects performed defectively, opting for the disadvantageous decks (A and B) more frequently than the advantageous decks (C and D). The LSS/I subjects, however, were normal.

tionary scale. In fact, first-order conditioning is more readily accomplished in “lower” animals, mediated by structures such as the amygdala. At the same time, higher-order conditioning is much more difficult to achieve in laboratory animals, and even when produced, is never as powerful as that accomplished in humans. Assuming the prefrontal cortices are important for higher-order conditioning, this helps account for the unique ability of humans to utilize concepts far removed from primary emotions (e.g., social feedback, praise, embarrassment) to guide decision making in everyday life (see Damasio, 1995a).

The right somatosensory/insular cortices Using the Gambling Task paradigm, we studied decision making in 12 subjects with right somatosensory/insular cortex (RSS/I) lesions, 6 subjects with left somatosensory/insular cortex (LSS/I) lesions, and 13 age- and education-matched normal controls (Bechara et al., 1997b). Eight of the RSS/I subjects were severely impaired on the task, and 4 were borderline (figure 73.8). By contrast, none of the LSS/I subjects was impaired; they played the game exactly the way the normal controls did, choosing more often from the advantageous decks. The results support the idea that the *right* somatosensory/insular region (but not the left) is another important component of the neural network subserving somatic marker activation and decision making.

The peripheral nervous system As outlined in the previous section, the somatic marker hypothesis proposes that body-related information, whether obtained directly from the body proper (the body loop) or indirectly from CNS-somatic-representing structures (the as-if-body loop), is critical for mechanisms of decision making. To investigate the part of the hypothesis related to the body-loop mode of operation, we tested the prediction that significant impairments of nervous system signaling, as seen in certain peripheral neuropathies, should be associated with impairments on the Gambling Task (Bechara et al., 1998b). The target subjects were 12 patients with peripheral neuropathy, mainly of the sensory type. They were compared with 7 demographically matched normal controls. We found that subjects with peripheral neuropathy performed defectively on the Gambling Task relative to controls, opting for the risky decks more frequently, especially as the task progressed. These results support the notion that on-line signaling concerning the body state is relevant for decision-making processes leveraged by reward and punishment.

Concluding comment

The somatic marker hypothesis provides a systems-level neuroanatomical and cognitive framework for reasoning, decision making, and emotional processing. A program of research aimed at testing various predictions from the hypothesis has yielded important new insights into the neural basis of decision making, some of the nonconscious and conscious operations that influence decision making, and some of the ways in which bioregulatory signals, including those that constitute emotion, play a role in decision making. The results thus far have been promising, and have supported several of the basic principles of the somatic marker hypothesis, including our emphasis on the role of neuroanatomical structures such as the ventromedial prefrontal cortex, the amygdala, and the right somatosensory/insular cortices in decision making and emotional processing.

ACKNOWLEDGMENTS Supported by Program Project Grant NINDS NS19632 and the Mathers Foundation. We thank Hanna Damasio and Ralph Adolphs for their collaboration in several of the studies reported here. We also thank Joseph Newman, University of Wisconsin, for a helpful approach to analyzing data from the Gambling Task.

NOTES

1. The discussion of connectional neuroanatomy here is based primarily on work in nonhuman primates, although we have every reason to believe that most of the key findings from this work would generalize accurately to humans.

2. This outcome may appear at odds with the finding reported earlier that the ventromedial prefrontal subjects failed to generate SCRs to emotionally charged pictures. We do not believe the outcomes are incompatible, though, because of the many differences in the nature of the stimuli and experimental paradigm, and the fact that the Gambling Task provides explicit feedback (reinforcement) to the subjects, whereas the previous paradigm did not.

Introduction

JOSEPH E. LEDOUX

The study of emotion was neglected by brain and cognitive scientists for decades, but it is now one of the major growth areas in neuroscience research. Studies in experimental animals are mapping pathways in great detail, and human research, spurred on by new developments in functional imaging, is confirming that the animal work applies to the human brain and is extending the findings in new directions. These are exciting times for emotion research.

In the introduction to the Emotion section in the first edition of this book, I said that there was not really a coherent group of neuroscientists who identified themselves as primarily emotion researchers. This situation has changed. It was fairly easy to assemble the cast for the first edition, but pretty difficult for this second edition, because of the large increase in the number of researchers working in the area, the greater range of topics being worked on, and the rapid expansion of human research on brain and emotion.

The chapters included in the present volume, I believe, give a flavor for the range of work being done today. Armony and LeDoux examine interactions between fear mechanisms and cognitive systems using neurobiological studies of rats and parallel connectionist modeling studies. McGaugh, Roozendaal, and Cahill examine the way emotionally arousing stimuli modulate declarative memory in rats and humans. Ono and Nishijo use single-unit recordings in primates to explore the neural systems involved in processing aversive and appetitive stimuli. Dolan focuses on the representation of fear in the brains of normal humans, using functional magnetic resonance imaging (fMRI) to map circuits. Pitman, Shalev, and Orr study abnormal fear, as in patients with post-traumatic stress disorder, using functional imaging and

other approaches. Finally, Davidson uses both functional imaging and electrophysiological recordings to study affective style in normal subjects and psychiatric patients.

Perhaps the overriding theme across all the chapters is the importance of the amygdala in emotional processes. This brain region is a central focus in each of the chapters, reflecting a remarkable degree of convergence of research findings about the neural basis of emotional processes across species and paradigms.

In hailing the progress that has been made though, it is important not to lose sight of several humbling facts. The first is that there is little agreement about what emotions are. Our crude conceptions have allowed us to move forward in identifying brain mechanisms, but surely we would be better off if we had a better understanding of what we are looking for.

Second, much of what we know about the detailed circuitry of emotion has come from studies of fear conditioning in rats. This has been a great way to jump-start the field, since subsequent research on humans, using fear conditioning and other fear-related tasks (for example, processing angry or threatening faces) has suggested that the animal findings are indeed relevant to the human brain. But much needs to be done in the study of fear. For example, the automatic fear reactions elicited by conditioned fear stimuli and threatening faces are just the beginning of an emotional episode. Once these responses have been elicited, typically without conscious participation, decision processes, and ultimately conscious experiences, come into play. Little is known about how these cognitive factors interact with more primitive emotion networks. And, in contrast to fear, work on even the basic mechanisms in other emotions has really just begun.

Third, it is conceptually appealing that the amygdala has been implicated in fear and some other emotions across paradigms and species, but we need to be cautious in interpreting these data. We have pretty much

gotten rid of the limbic system theory of emotions and its overambitious explanation of all emotions as functions of one big system, and we should not replace it too quickly with the amygdala theory of emotion. We should not, in other words, generalize from the research on fear to other emotions and assume that the amygdala is involved. The amygdala could be involved in several emotions because it plays the same role in each or because it plays different roles. There are about 13 different nuclei of the amygdala, and each has several subnuclei with unique connections. For fear conditioning in rats, the anatomical resolution at this point is approaching the subnuclei. Until the circuitry underlying the amygdala's contribution in different emotions is known in similar detail, we have to be very careful about what we conclude.

Finally, it is important to realize that the neural mechanisms underlying the expression of emotional responses, like the defense responses associated with the fear system, are not necessarily the mechanisms that give rise to the subjective feelings, like the feeling of being afraid, that occur when these systems are active in the human brain. We know little at this point about the brain mechanisms of subjective emotional experience. It is possible that the topic of emotional experience is really more about the nature of consciousness than the nature of emotion (for more about this topic, see Armony and LeDoux, chapter 74).

Emotion research is likely to continue at a rapid pace. It is important for researchers in this area to keep asking themselves what it is they are studying and to be especially cognizant of the limitations of data they collect. By the time the next edition of this book is published, one may hope that some of the conceptual problems will have been solved and that a large body of research findings will have begun to give us a coherent picture of how our brains make emotions.

How Danger Is Encoded: Toward a Systems, Cellular, and Computational Understanding of Cognitive-Emotional Interactions in Fear

JORGE L. ARMONY AND JOSEPH E. LEDOUX

ABSTRACT The neurobiology of cognitive-emotional interactions can be better understood by studying the neural mechanisms of well-defined and experimentally tractable aspects of particular emotions and by exploring their relationship with specific cognitive processes. In this chapter we focus on fear, because the neural bases of this emotion have been worked out better than any other. Specifically, we describe recent findings on behavioral and physiological aspects of fear conditioning. This issue is approached from both a systems and a cellular point of view, combining empirical studies with computational modeling. The interactions of the fear network with some of the neural systems associated with perception, attention, declarative memory, and consciousness are discussed.

Introduction

The relationship between cognition and emotion has been a central issue in the study of the mind throughout history. Nevertheless, the nature of this relation, especially at the neural level, is still poorly understood. Part of the problem, it would seem, is that the broad concepts of “cognition” and “emotion” refer to collections of disparate brain processes, rather than to real functions performed by the brain. For example, within the domain of “cognition,” the terms *perception*, *memory*, *attention*, and *action* more closely characterize processes mediated by the brain. But each of these, in turn, is also a shorthand description of more fundamental processes that better approximate the neural functions in question—vision versus touch, implicit versus explicit memory, attention versus preattentive processes, and so on. And even these can be further broken down into more fundamental processes; visual perception, for instance, consists of distinc-

tive functional components, such as form, color, motion processing, and so on. Similarly, emotions are made up of component functions (subjective experience, stimulus evaluation, physiological responses, feedback, elicited behaviors, voluntary behavior, etc.). Though substantial progress has been made over the past several decades in understanding cognitive processes by studying the fundamental components as brain functions (as illustrated in the present volume), emotion has not been studied extensively in this way. There are historical and conceptual reasons why emotion was not included within cognitive science (see LeDoux, 1996) and, accordingly, was not a major research focus within cognitive neuroscience either. Nevertheless, there is no reason why emotions cannot also be explored as specific information-processing functions of the brain. In fact, segregating both “emotion” and “cognition” into elementary processes, grounded in neural systems, is likely to be a far more powerful approach to understanding how the processes in question work than one that ignores these considerations.

In this chapter, we will outline an approach to understanding cognitive-emotional interactions in the brain, examining the problem through explorations of one specific emotion—fear. We lay out what the neural components of the fear system are, as well as the processes subserved by these, and then ask how the processes in that neural system relate to components of systems that mediate various cognitive processes. We examine the problem from behavioral, neural-systems, and cellular points of view. By drawing upon different levels of analysis and ensuring that theories proposed at one level correspond with theories of other levels (see Churchland and Sejnowski, 1992), we hope to gain a better understanding of the neurobiological bases of cognitive-emotional interactions. Furthermore, although much of

JOSEPH E. LEDOUX Center for Neural Science, New York University, New York, N.Y.

the work that rationalizes this approach is based on empirical findings, we have also recently explored some of the issues through computational modeling, and will draw on both kinds of studies here.

WHY FEAR? Fear is an emotion that is particularly important to human and animal existence. It is a normal reaction to danger and occurs often in daily life. A number of psychiatric conditions that afflict humans (including panic attacks, phobias, generalized anxiety, and posttraumatic stress syndrome) are likely to represent disorders of the fear system (Charney et al., 1995; LeDoux, 1996; Öhman, Flykt, and Lundqvist, *in press*). Also, fear is particularly amenable to laboratory experimentation: It can be readily elicited, and a number of quantitative measures of fear can be used. Even if through studies of fear we were to learn only about fear-related processes, rather than about “emotion” in general, these findings would still be an important achievement.

FEAR CONDITIONING AS A MODEL APPROACH TO FEAR There are a number of experimental tools for studying fear and anxiety in animals and humans. One of the simplest and most commonly used is classical aversive conditioning, or fear conditioning. With this procedure, meaningless stimuli acquire affective properties when they occur in conjunction with a biologically significant event. When a conditioned stimulus (CS), often a tone, is repeatedly presented to a rat in association with an aversive unconditioned stimulus (US), such as a mild electric shock to the feet, the rat will, when presented with the CS in the absence of the US, exhibit a complex set of fear responses. These responses include increases in heart rate and blood pressure, “freezing” (absence of all movements but those associated with breathing), and hormone release, among others. The responses are not themselves learned, but they are hardwired (genetically specified) reactions to naturally occurring threats. Through fear conditioning, novel environmental stimuli can gain access to neural circuits that control hardwired, evolutionarily acquired, defense responses. Fear conditioning is a very efficient form of learning. It can be acquired very quickly (in as little as a single trial) and is very difficult to extinguish. It occurs throughout the phyla, and within vertebrates, including humans, it appears to involve very similar neural mechanisms across species. Much of the background information about fear conditioning is summarized in LeDoux (1996).

NEURAL CIRCUITRY OF FEAR CONDITIONING A large number of studies, using different experimental paradigms and measures of conditioned fear responses, have

consistently supported the notion that the amygdala is the key structure in the neural system involved in learning about stimuli that signal threat (e.g., Davis, 1992; Fanselow, 1994; Kapp et al., 1992; LeDoux, 1996). The amygdala receives and integrates information about the CS, as well as information about context and internal states, and controls the various conditioned response networks in the brain stem. In this section, we summarize findings about the pathways involved in fear conditioning to auditory stimuli, since these are the best understood (more detailed descriptions can be found in Armony and LeDoux, 1997a; LeDoux, 1995, 1996).

An acoustic CS is transmitted through the auditory system to the auditory thalamus—the medial geniculate body (MGB). From there, information is conveyed to the amygdala by way of two parallel pathways. A direct projection originates primarily in the medial division of the MGB (MGm) and the associated posterior intralaminar nucleus (PIN). A second, indirect, pathway conveys information from all areas of the MGB to auditory cortex, from where, via several corticocortical links, it is transmitted to the amygdala. The direct thalamic pathway is believed to provide rapid but imprecise information, whereas the auditory cortex provides slower but more detailed representation to the amygdala (e.g., LeDoux, 1996). Lesion studies have demonstrated that either pathway is sufficient for conditioning to a simple stimulus, such as a pure tone (Romanski and LeDoux, 1992). Although auditory cortex appears not to be necessary for simple frequency discrimination (discussed later; Armony et al., 1997b), it may become crucial for higher levels of processing involving complex sounds (e.g., Whitfield, 1980).

Anatomical and physiological studies suggest that the lateral nucleus of the amygdala (LA) is a major site of termination of both thalamic and cortical auditory inputs (Amaral et al., 1992; Bordi and LeDoux, 1992; LeDoux et al., 1990; Romanski et al., 1993). In fact, single cells in LA receive convergent inputs from the auditory thalamus and cortex (Li, Stutzmann, and LeDoux, 1996). Information flows from LA to the central nucleus (CE) over well-defined intra-amygdala circuits (for a review, see Pitkänen, Savander, and LeDoux, 1997). The central nucleus appears to be the interface with the motor systems that are involved in controlling conditioned responses (Davis, 1992; Kapp et al., 1992). Thus, whereas lesions of CE interfere with the expression of fear responses of all types, lesions of areas to which CE projects interfere with select responses. For example, lesions of the lateral hypothalamus interfere with sympathetic-nervous-system-mediated responses (such as changes in blood pressure) whereas lesions of the central gray interfere with behaviorally conditioned re-

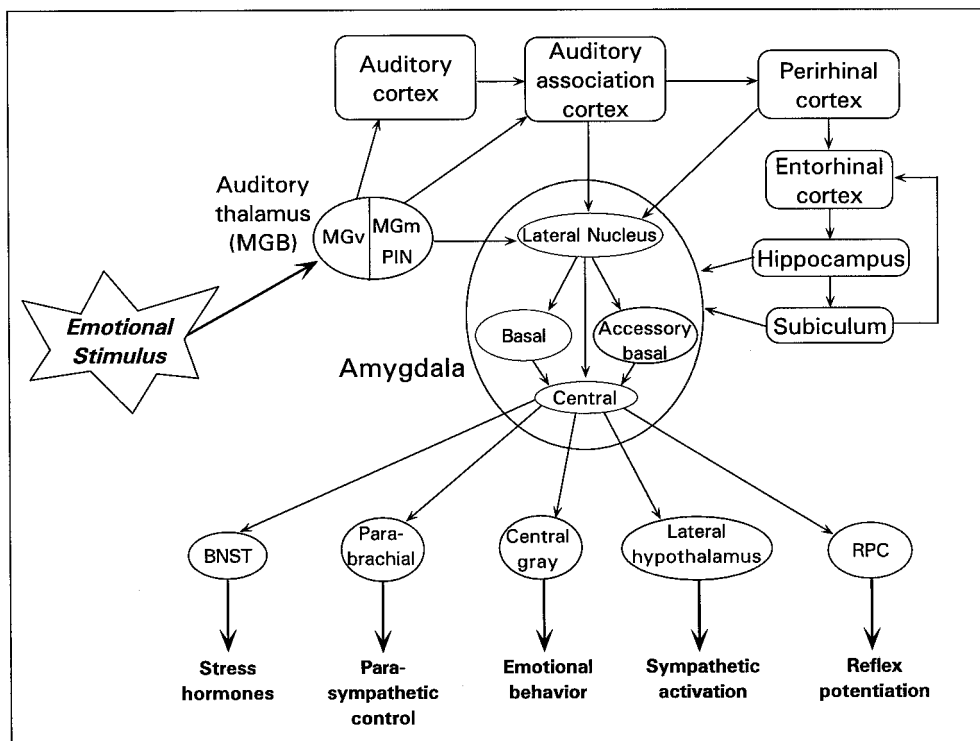

FIGURE 74.1 Schematic of the circuit underlying auditory fear conditioning. The lateral nucleus of the amygdala receives a hierarchical cascade of information from sensory areas in the thalamus and neocortex, as well as inputs from higher-order association neocortical regions and hippocampal formation.

Through intra-amygdala processing, information reaches the central nucleus, which controls the expression of different emotional responses. BNST, bed nucleus of the stria terminalis; RPC, nucleus reticularis pontis caudalis. (Modified from Armony and LeDoux, 1997a.)

sponses (e.g., freezing). A schematic of the neural circuit underlying auditory fear conditioning is depicted in figure 74.1.

Although most of the findings about the neural basis of fear conditioning have been obtained from studies of animals, particularly rats, recent studies suggest that analogous brain regions and mechanisms are involved in human fear conditioning. For example, patients with temporal lobe lesions that include the amygdala (LaBar et al., 1995) or are restricted mainly to it (Bechara et al., 1995) have shown deficits in fear conditioning and in the perception of fear in facial expressions (Adolphs et al., 1994) and voices (Scott et al., 1997). In addition, functional imaging studies have now shown activation of the amygdala during fear conditioning (Büchel et al., 1998; LaBar et al., 1998) and while processing faces and other emotional stimuli (Whalen et al., 1998).

Simulating circuits: A computational model of the fear conditioning network

In our attempt to understand the neural mechanisms of fear processing, we have constructed a computational model of the fear conditioning system based on the em-

pirical findings described in the preceding section. The model has captured some functional aspects of the circuitry and underlying processes surprisingly well, and it has made some novel predictions that have been borne out by subsequent empirical studies.

THE MODEL A diagram of the basic architecture of the network used in the simulations described here is shown in figure 74.2. The essential elements of the model are the following (more details can be found in Armony et al., 1995, 1997a, 1997b):

- *Processing units:* Simple, nonlinear summing units are used as a first approximation of the behavior of a single neuron (or a neuronal assembly that redundantly codes for the same piece of information). The response of a unit to a given input pattern is thought to represent the time-averaged neuronal firing rate.

- *Architecture:* Information is coded and processed in two parallel systems; one that involves more elaborate representations but less direct connections with response systems (the indirect, or “cortical,” pathway) and another that involves cruder representations but more direct connections with the response systems (the direct, or “subcortical,” pathway). These two systems

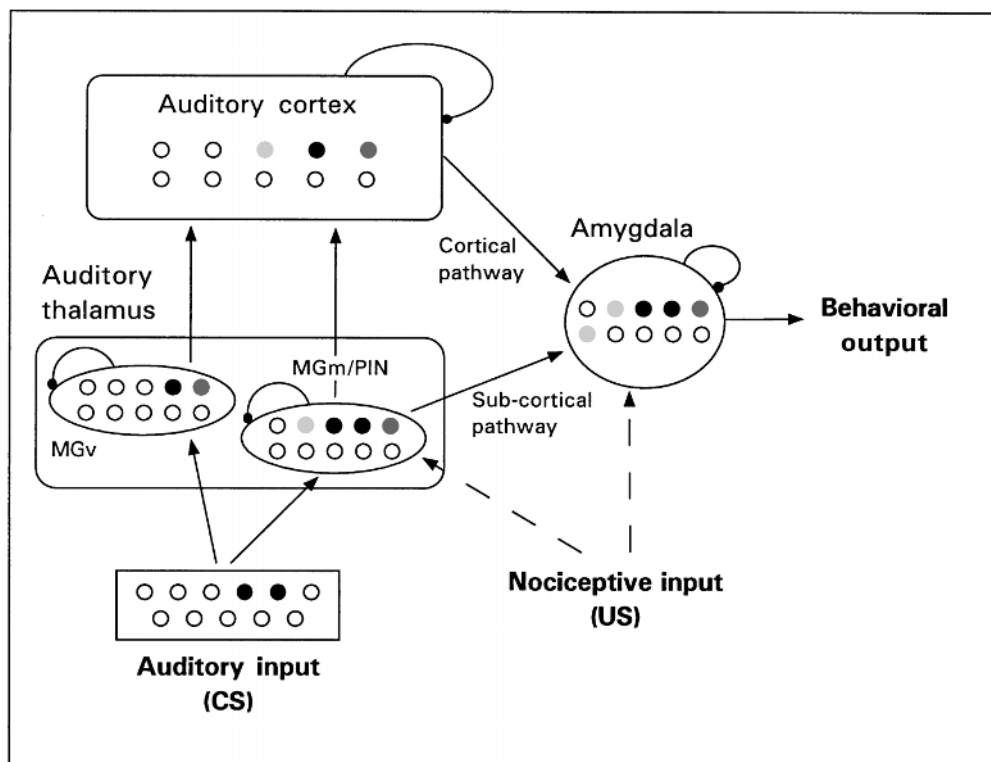

FIGURE 74.2 Architecture of the network used in the simulations of fear conditioning. Modules of nonlinear, mutually inhibitory units represent the main structures of the fear circuit. A typical pattern of activity is schematized by representing unit activation with gray shadings (solid circles, maximum activation; open circles, zero activation). Connections between modules are feedforward and excitatory, and are modified

through an extended Hebbian learning rule (see text for details). Dashed arrows indicate positive, nonmodifiable connections. MGv, ventral division of the medial geniculate body (MGB); MGm, medial division of the MGB; PIN, posterior intralaminar nucleus; CS, conditioned stimulus; US, unconditioned stimulus. (Adapted from Armony et al., 1997b.)

converge on the amygdala—the effector system for fear responses. Units within a module are mutually inhibitory. The strength of this lateral inhibition is used to capture the differences in the response properties (broad versus narrow receptive fields) of the extralemniscal MGB (MGm/PIN) and amygdala on the one hand, and lemniscal MGB (MGv) and auditory cortex on the other hand.

- **Sensory input:** Auditory input is simulated by a set of overlapping patterns of activity, representing pure tones of contiguous frequencies (arranged along an arbitrary scale). During the conditioning phase, one of the stimuli serves as a CS. The US is a positive quantity directly added to the input term of all units in the MGm/PIN and amygdala modules during conditioning.

- **Learning:** We relied on a simple modification of the Hebbian learning rule, in which connection strengths are increased between correlated units and decreased for uncorrelated units. This, together with the lateral inhibitory connections, represents a variant of standard competitive learning rules (Rumelhart and Zipser, 1986).

EXPERIMENTS WITH THE MODEL

Conditioning-induced plasticity: From units to behavior Single-unit recording studies have shown that individual cells in the auditory thalamus, auditory cortex, and lateral amygdala have characteristic frequency receptive field profiles, and that these are altered through fear conditioning. We examined whether this pattern might also occur in the model. Prior to conditioning, and as a result of the presentation of simulated acoustic tones, units developed frequency receptive fields (RFs); that is, each unit responded only to a subset of contiguous inputs, centered on a best frequency (BF). Subsequent conditioning (CS-US pairing) resulted in some units showing frequency-specific retuning of their RFs, such that there was a shift of the BF toward the CS. An example of an amygdala RF shift is shown in figure 74.3A. In the model, as in real brains, the shifts occurred in the MGm, auditory cortex, and amygdala, but not in the MGv. The unit receptive-field changes in the model thus closely mirrored the changes observed in the exact same areas in animal experiments (Bordi and LeDoux, 1993; Weinberger, 1995). It should be noted that the model

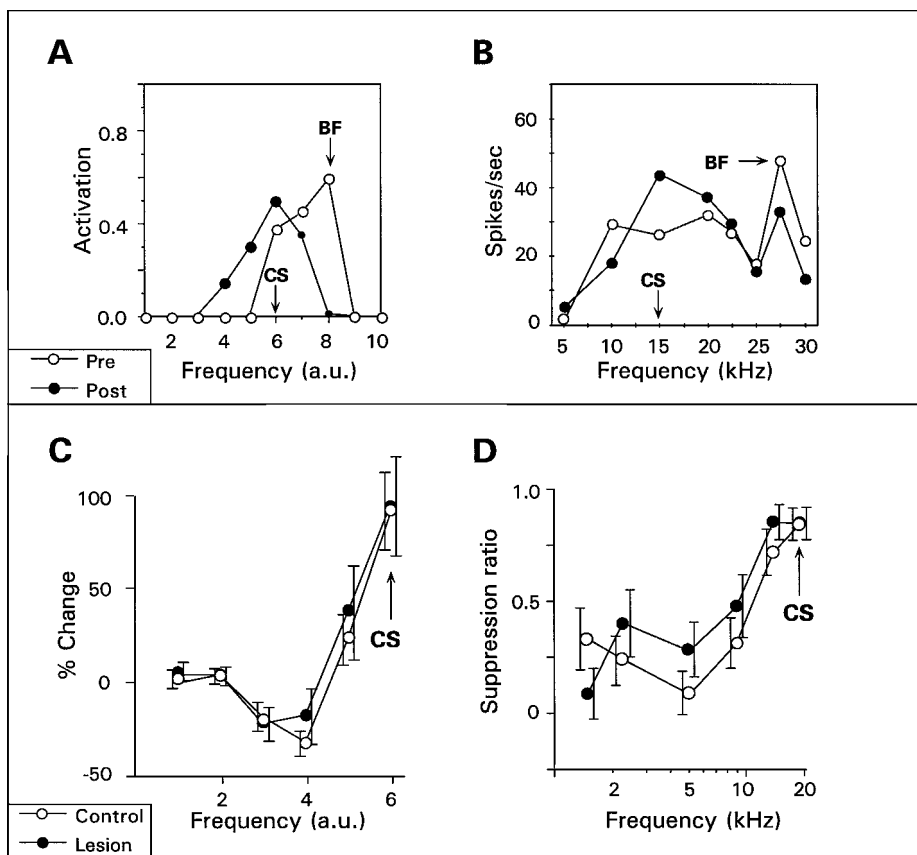

FIGURE 74.3 Examples of conditioning-induced plasticity in receptive fields (RFs) of amygdala units in the computational model (A), and of amygdala neurons in rats (B), before (Pre, open symbols) and after (Post, filled symbols) conditioning. In both cases, fear conditioning resulted in a shift of RFs, such that the conditioned stimulus (CS) became the new best frequency (BF). This stimulus re-representation, in turn, resulted in increases of fear responses to the CS and adjacent frequen-

cies in the model (C; open symbols) and in rats (D; open symbols), in the form of a stimulus generalization gradient (SGG). Cortical lesions prior to conditioning did not have an effect on the width of the SGG in either case (C, D; filled symbols). a.u., arbitrary units. (A, adapted from Armony et al., 1995; B, based on data from Bordi and LeDoux, 1993; C and D, modified from Armony et al., 1997b.)

was in no way programmed to exhibit these changes. The changes instead occurred because of the network architecture: The areas that changed were areas that receive inputs from the CS and US.

The re-representation of the input patterns at the single-unit level, based on their learned aversive value, is reflected in the behavioral output of the network as an increase in the response to the CS and adjacent frequencies in the form of a stimulus generalization gradient (SGG), shown in figure 74.3C (open symbols). Similar gradients are observed in animal experiments (figure 74.3D; see Armony et al., 1997b).

Auditory cortex lesions and stimulus generalization Once we found that the basic physiological and behavioral observations were quantitatively reproduced by the model, it became possible to use the model to formulate new predictions. We were particularly interested in investigating the relative contributions of the thalamic and cor-

tical inputs to the amygdala in fear conditioning. Because the cells of origin in the direct thalamic pathway have broader receptive fields, we hypothesized that removal of the cortical input to the amygdala would cause fear responses to generalize more broadly to stimuli other than the CS. However, the simulations showed that lesion of the corticoamygdala pathway in the model did not affect the stimulus generalization gradient (figure 74.3C). Further analysis indicated why this result occurred. Although individual thalamic units in the MGm/PIN, which provide the direct projection to the amygdala, may not be capable of discriminating similar stimuli (because of their broad RF), the structure as a whole is a much better stimulus discriminator, because it relies on population coding. Interestingly, subsequent studies in rats confirmed the predictions of the model; that is, removal of auditory cortex did not have a significant effect on the conditioned SGG, as shown in figure 74.3D. This finding shows that, contrary to what was

previously thought (see Jarrell et al., 1987; LeDoux, 1995), the direct thalamoamygdala pathway is capable of supporting some aspects of stimulus discrimination. Further studies are needed to realize the full capacity, and limitations, of the thalamic inputs to the amygdala. The key point though is that the modeling study gave an unexpected result that led us to perform studies in animals. The latter study showed that the modeling result, though unexpected, was correct.

Cellular mechanisms

With key aspects of the circuitry now understood in some detail, investigators have turned to an analysis of cellular mechanisms underlying conditioning. It is generally accepted that classical conditioning involves the neural intersection of pathways transmitting information about the CS and US. The US somehow changes the strength of the synaptic connections in the CS processing pathway, allowing the CS to have an amplified effect. The lateral amygdala (LA), the sensory interface of the amygdala, is a site of CS-US convergence. Thus it is important to understand how sensory information is represented in LA neurons—and how this representation is altered through fear conditioning.

STIMULUS PROCESSING IN THE LATERAL AMYGDALA
Most studies of sensory processing by amygdala cells have involved auditory stimuli in rats (e.g., Bordi and LeDoux, 1992, 1993; Quirk, Repa, and LeDoux, 1995; Romanski et al., 1993) and visual stimuli in primates (reviewed in Rolls, 1992). In rats, LA cells have short latency responses to simple auditory stimuli. These latencies must correspond to direct transmission from the thalamus, since they are similar to the earliest latencies in areas in auditory cortex that project to the amygdala. Some cells habituate quickly to repeated unreinforced presentations of the same stimulus, but they respond strongly if the stimulus is changed or if it is paired with a US. That is, these cells act as novelty detectors: they learn to ignore stimuli that produce no consequences, and hence have no emotional meaning. Some cells in LA seem to respond preferentially to species-specific stimuli with intrinsic affective value. For example, in rats, LA cells with auditory responses have relatively high thresholds (about 30–50 dB above the primary auditory system) and tend to prefer high-frequency stimulation (16–30 kHz tones). This frequency range is similar to that of the warning calls that rats emit when threatened (Blanchard et al., 1991). In primates, face identity and expression play an important role in social behavior. A group of cells in the monkey amygdala responds primarily to faces (see Rolls, 1992),

and recent imaging studies in humans, mentioned earlier, show that emotional faces activate the amygdala. Finally, again in rats, most cells that respond to auditory stimuli also respond to somatosensory stimulation (Romanski et al., 1993) and, therefore, are potential sites of CS-US integration during auditory fear conditioning.

CONDITIONING-INDUCED NEURAL PLASTICITY IN LA
Neurons in several components of the fear circuit exhibit changes in their response to the CS after conditioning. Specifically, cells in the MGm, auditory cortex, and amygdala develop conditioning-induced plasticity (Quirk, Armony, and LeDoux, 1997; Quirk, Repa, and LeDoux, 1995; Weinberger, 1995). In LA some cells develop short-latency increases to a tone CS after it has been paired with a foot-shock US. The earliest latency of this plasticity falls within 10–20 ms after tone onset (Quirk, Repa, and LeDoux, 1995). These changes cannot be accounted for by corticoamygdala projections, since the earliest plasticity observed in auditory association cortex does not occur until 20–40 ms after tone onset (Quirk, Armony, and LeDoux, 1997). Moreover, it is unlikely that plasticity in LA merely reflects active plasticity transmitted from the auditory thalamus either, as thalamic conditioning-induced plasticity appears to take longer (for a discussion, see Quirk et al., 1996). Neural plasticity in LA also develops in fewer trials (1–3 CS-US pairings) than auditory cortex (6–9 pairings) (Quirk, Armony, and LeDoux, 1997). Interestingly, amygdala lesions do not have an effect on onset plasticity in auditory cortex (Armony, Quirk, and LeDoux, 1998). These findings suggest that onset plasticity in both LA and auditory cortex develop independently, and that both are driven by direct inputs from the thalamus. Conditioning-induced plasticity is also observed in other amygdala subnuclei, such as the basal and central nuclei (Muramoto et al., 1993; Pascoe and Kapp, 1985). Plasticity in these areas, however, occurs at later times than in LA (e.g., 30–50 ms after CS onset in the central nucleus; Pascoe and Kapp, 1985). These latency differences between the input and output nuclei suggest that significant processing occurs within amygdala circuits.

Plasticity of synaptic transmission in LA has also been studied using long-term potentiation (LTP) in the thalamoamygdala pathway (Clugnet and LeDoux, 1990; Rogan and LeDoux, 1995); LTP induction results in an enhanced processing of auditory stimuli through this pathway (Rogan and LeDoux, 1995), indicating that natural stimuli can make use of artificially induced plasticity. Most important, though, natural learning (fear conditioning) also enhances the processing of auditory stimuli in the same way (Rogan, Stäubli, and LeDoux, 1997). Thus fear conditioning induces an LTP-like neural change in LA. Together with the unit-recording studies

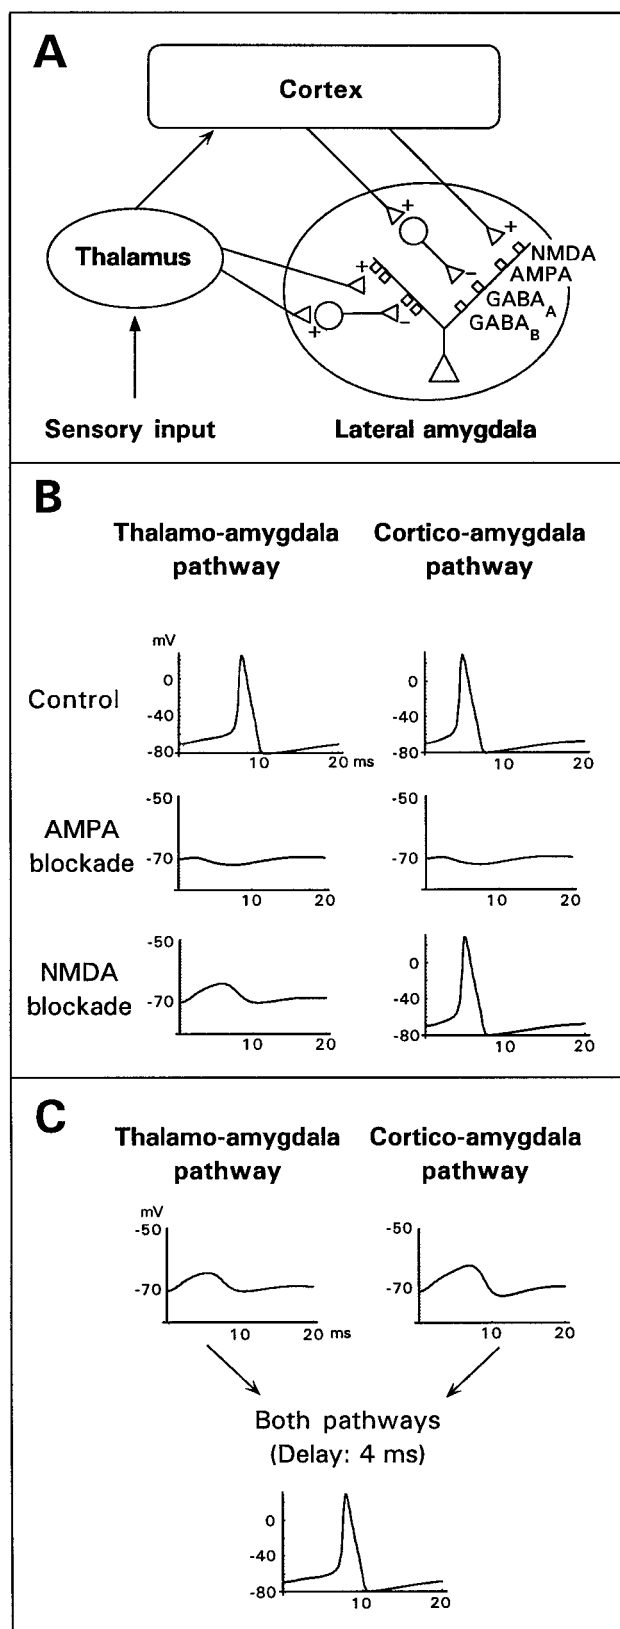

FIGURE 74.4 (A) Schematic of the biophysical model of an amygdala neuron. The neuron receives excitatory inputs acting upon AMPA and NMDA receptors, and feedforward inhibition via GABA_A and GABA_B receptors. (B) Effects of AMPA and NMDA blockade on the model neuron's response to thalamic and cortical stimulations. Removal of AMPA currents blocks action potential generation in both cases, but blocking of NMDA receptors only has an effect on the thalamic pathway, consistent with experimental findings (see text for details). (C) Joint stimulation of the thalamic and cortical pathways (with a short delay, meant to represent the different latencies in normal auditory transmission) elicits suprathreshold response (action potential) in the model neuron, even when stimulation of each pathway individually only results in subthreshold responses.

described previously, these findings point toward synaptic changes in the input pathways to the amygdala as being important in the learning experience.

BIOPHYSICAL MODELING OF AMYGDALA NEURONS
With more information becoming available about cellular mechanisms within the amygdala, it is becoming possible to explore this region using neuronal models. In this spirit, we have recently begun to expand our network model to incorporate biophysical data. As a first step, we have explored interactions between thalamic and cortical auditory inputs to single LA cells.

We developed a simplified biophysical model of an amygdala neuron receiving convergent inputs from the thalamic and cortical pathways (Armony and LeDoux, 1997b; Li, Armony, and LeDoux, 1996) to explore how information arriving from both pathways is integrated within individual amygdala cells. The model neuron (see figure 74.4A), represented as a single compartment, has six ion-channel types: two of them, sodium and potassium, are voltage-gated and modeled using the standard Hodgkin-Huxley formalism; the other four are ligand-gated. They represent the excitatory and inhibitory synaptic currents activated by the glutamate receptors (AMPA and NMDA) and GABA receptors (GABA_A and GABA_B), respectively. These channels are represented by a two-state model, proposed by Destexhe, Mainen, and Sejnowski (1994). The parameters for the AMPA and NMDA currents were derived from patch-clamp data from amygdala neurons (Weisskopf and LeDoux, 1997), whereas those for GABA currents were obtained from previously published hippocampus data (Otis and Mody, 1992), since no amygdala data were available. This simple model captured a number of physiological observations that have been previously reported:

1. Both thalamic and cortical pathways depend on AMPA receptors for synaptic transmission. The thala-

moamygdala pathway also requires NMDA activation for normal transmission (figure 74.4B; see Li, Phillips, and LeDoux, 1995; Li, Stutzmann, and LeDoux, 1996).

2. Blockade of GABA_A receptors results in an increase of evoked action potentials elicited by thalamic or cortical stimulation (cf. Li, Armony, and LeDoux, 1996).

3. The differential contributions of GABA_A and GABA_B to short- and long-delay inhibition, respectively, can be accounted for by a simple feedforward inhibitory circuit (see Li, Armony, and LeDoux, 1996).

4. Combined inputs from thalamic and cortical projections (with a short delay between them) can elicit suprathreshold responses in amygdala cells, when each input individually only evokes subthreshold responses (figure 74.4C; see Li, Woodson, and LeDoux, 1997).

As with the connectionist model described in previous sections, once the validity of the model is established by its capacity to account for several of the key phenomena observed in in-vivo and slice intracellular experiments, we can use the model to make new predictions that will guide future physiological studies. Moreover, we can use these simplified biophysical models of individual neurons as computational units in the systems model of the fear network described earlier, to further explore the relations between neural and behavioral processes. This approach is possible given the modular nature of the network model. In other words, the amygdala module can be replaced with a biophysically based module, leaving the connections from the other modules intact and allowing the biophysical properties in the amygdala to operate within a larger, realistic network. This model might prove useful as a means of testing hypotheses about the synaptic and cellular basis of fear learning.

Cognitive-emotional interactions in fear

Identification of the neural system involved in fear processing paves the way for considering how key elements of that system interact with brain systems involved in certain aspects of cognitive processing. In this section, therefore, we will examine how the amygdala interacts with brain systems involved in aspects of perception, attention, memory, and consciousness.

PERCEPTION AND FEAR The amygdala receives inputs from cortical sensory processing regions of each sensory modality (Amaral et al., 1992; Turner, Mishkin, and Knapp, 1980) and can, as in the case of fear conditioning, determine whether stimuli processed through those channels are sources of potential danger. However, the amygdala also projects back to cortical sensory processing areas (Amaral et al., 1992). This anatomical arrangement suggests that in addition to

processing the emotional significance of external stimuli transmitted to the amygdala from cortical areas, the amygdala might also influence the processing that occurs in these areas. In contrast, while the amygdala also receives and processes the significance of sensory stimuli directly from sensory areas in the thalamus, it does not project back to these areas (see LeDoux, Ruggiero, and Reis, 1985).

The amygdala only receives inputs from the late stages of cortical sensory processing, but it projects back to the earliest stages (Amaral et al., 1992). As a result, once the amygdala is activated by a sensory event from the thalamus or cortex, it can begin to regulate the cortical areas that project to it, controlling the kinds of inputs it receives. The amygdala also influences the cortical sensory process indirectly, by way of projections to various "arousal" networks, including the basal forebrain cholinergic system, the brainstem cholinergic system, and the locus coeruleus noradrenergic system, each of which innervates widespread areas of the cortex. Thus, once the amygdala detects danger, it can activate these arousal systems, which could then influence sensory processing (e.g., Aston-Jones et al., 1996; Gallagher and Holland, 1994; Kapp et al., 1992; Weinberger, 1995).

FEAR AND SELECTIVE ATTENTION Selective attention is believed to occur in cortical areas and to result from the allocation of processing resources so that task-relevant (i.e., attended) stimuli are focused on at the expense of competing (unattended) ones (Duncan, Humphreys, and Ward, 1997). However, if this mechanism operated unconditionally, deleterious consequences could occur in some situations. For example, if a predator appeared somewhere outside of the focus of attention, it would be ignored until it was too late, because of the reduced cortical representation given to it by attentional filtering processes. However, we are generally able to respond to threats arising outside our focus of attention (Öhman, Flykt, and Lundqvist, in press). The direct thalamo-amygdala pathway may hold the key.

Using a computational model, we tested the hypothesis that the thalamoamygdala pathway might constitute an attention-independent channel that provides the amygdala with information about threat signals that occur outside (or inside) the focus of attention. The model was based on the fear conditioning network described earlier, integrated with a model of selective attention proposed by Cohen, Dunbar, and McClelland (1990). The architecture of the network is shown in figure 74.5. Two parallel processing streams, representing different aspects of the environment (such as right and left auditory hemifields) or task demands (such as color naming

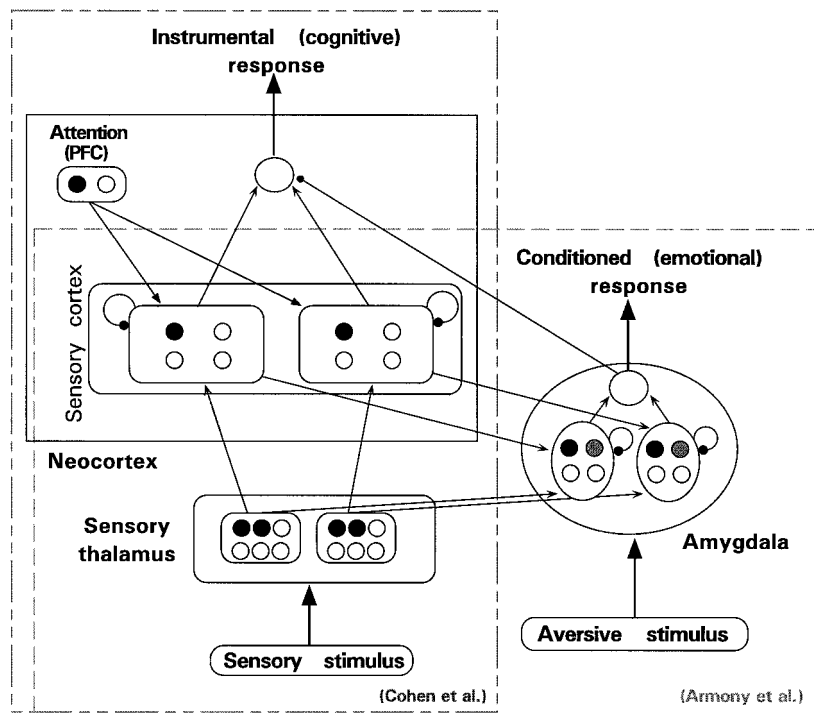

FIGURE 74.5 Architecture of the integrated network used in the simulations of attention-emotion interactions. The network combines the original fear network described in Armony et al. (1995, 1997b; see figure 74.2), and the model of selective attention of Cohen, Dunbar, and McClelland (1990). Sensory information flows along two parallel processing streams, representing different dimensions of the stimulus space. The

two streams compete for cortical resources, which are allocated by externally set attentional inputs. Emotional (fear) responses have the capacity to inhibit instrumental responses. Connections with filled arrowheads correspond to nonmodifiable excitatory weights, open arrowheads represent modifiable excitatory connections, and circular arrowheads represent inhibitory connections. PFC, prefrontal cortex.

versus word reading in the Stroop task), compete for the limited pool of processing resources to determine behavioral responses. Selective attention units were externally set to bias one representation over the other, depending on where attention was allocated (Duncan, Humphreys, and Ward, 1997). The direct thalamo-amygdala pathway was not subject to attentional bias. The overall behavioral output of the network resulted from competition between instrumental (cognitive) responses, determined by output of the cortical module, and fear-related responses, elicited by amygdala activation. This response competition was implemented in an asymmetrical fashion, so that the fear response had the capacity to inhibit instrumental responses. This design was meant to represent, in a simplified manner, empirical observations that fear reactions can interrupt ongoing behavior in favor of danger-elicited survival responses (Bouton and Bolles, 1980). The results of the simulations predict that lesions of the direct thalamic projections to the amygdala will interfere with fear responses to an unattended CS. The model also suggests that significant interference in stimulus processing in cognitive-attentional tasks, such as the Stroop word-

color interference task, can occur when some of the stimuli have acquired strong negative affective value through fear conditioning (Armony et al., 1996). Thus the model shows how emotional processing can operate independently of, and modulate the focus of, attentional mechanisms.

Electrophysiological experiments support the view that the amygdala regulates cortical attentional/perceptual processing. Stimulation of the amygdala results in a desynchronization of cortical EEG, which typically occurs when attention is directed to some stimulus (Kapp, Supple, and Whalen, 1994). This effect is mediated by cholinergic projections from the basal forebrain. Furthermore, during fear conditioning some cells in the auditory cortex exhibit an increase in neural activity during the CS just before the occurrence of the US (figure 74.6; Quirk, Armony, and LeDoux, 1997). These cells may be involved in the direction of attention to the spatiotemporal aspects of the US. Damage to the amygdala prevents the emergence of this conditioned neural response (Armony, Quirk, and LeDoux, 1998). This fact does not imply that the amygdala is involved in all aspects of cortical attention, but rather that it may

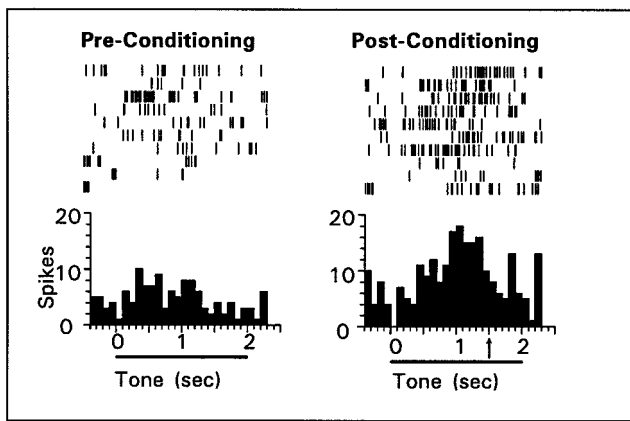

FIGURE 74.6 Example of an auditory cortex neuron showing long-latency conditioned tone responses. Before conditioning, the cell did not respond to the tone. Following CS-US pairings, however, the neuron developed a late significant tone response, starting at about 500 ms after tone onset, and reaching its peak at 1500 ms, which was the onset of the US during conditioning (indicated by the arrow). Bin size is 100 ms. (Adapted from Armony, Quirk, and LeDoux, 1998.)

be involved in the direction and focusing of attention toward dangerous stimuli or stimuli that predict danger. As we pointed out, amygdala regulation of the cortex could involve the facilitation of processing of stimuli that signal danger even if such stimuli occur outside of the attentional field (Armony et al., 1996, 1997a).

DECLARATIVE MEMORY AND FEAR It is now widely recognized that there are a variety of memory systems in the brain, some of which work in parallel (see Cohen and Eichenbaum, 1993; Gaffan, 1994; Squire and Zola, 1996). For example, information about stimuli associated with painful or otherwise unpleasant experiences is stored in the amygdala and related brain regions. This system mediates the emotional reactions that are elicited when these stimuli are reencountered. It can operate at an implicit or unconscious level (LeDoux, 1996; Öhman, Flykt, and Lundqvist, in press). However, we usually have explicit or conscious memories about emotional situations as well. These, like other explicit memories, are mediated by the medial temporal lobe memory system involving the hippocampus, rhinal cortex, and related cortical areas (Gaffan, 1994). The implicit memories of emotional events have been called *emotional memories*, and the explicit memories have been termed *memories about emotions* (LeDoux, 1996). Implicit emotional memories are automatically elicited in the presence of trigger stimuli and do not require conscious retrieval or recall, whereas explicit memories of emotion are retrieved consciously. In humans, damage to the amygdala interferes with implicit

emotional memories but not explicit memories about emotions, whereas damage to the medial temporal lobe memory system interferes with explicit memories about emotions but not with implicit emotional memories (Bechara et al., 1995; LaBar et al., 1995). For example, patients with amygdala lesions do not exhibit conditioned fear responses to the CS but remember that the CS was related to the US, while patients with hippocampal damage exhibit conditioned responses but have no memory of the CS-US pairing experience.

As described earlier, in a set of physiology studies of fear conditioning in rats, we determined that short-latency plasticity develops independently in neocortex and amygdala (see figure 74.7). These findings provide further support, at a cellular level, for the notion that the declarative and emotional memory systems may, to some extent, operate in parallel.

While explicit memories with and without emotional content are mediated by the medial temporal lobe system, those with emotional content differ from those without such content. The former tend to be longer lasting and more vivid (see Christianson, 1992). Studies by McGaugh and colleagues (McGaugh, Cahill, and Roozental, 1996) have shown that stories with emotional content are remembered better than similar stories lacking emotional implications. Lesions of the amygdala or systemic administration of a beta-adrenergic antagonist prevent this effect (see McGaugh, Cahill, and Roozental, 1996). In animal studies, lesions of the amygdala significantly accelerate the extinction rate of plasticity in auditory cortex neurons (Armony, Quirk, and LeDoux, 1998), as shown in figure 74.7. Thus both behavioral and physiological findings suggest a role for the amygdala in the enhancement and/or consolidation of declarative memories with affective content.

FEAR AND CONSCIOUSNESS We have described findings about how the brain process emotions, particularly fear, without mentioning conscious feelings (i.e., the experience of being afraid). Nevertheless, consciousness is an important part of the study of emotion and other mental processes. Our hypothesis is that the mechanism of consciousness is the same for emotional and nonemotional subjective states and that what distinguishes these states is the brain system that consciousness is aware of at the time.

We are far from solving what consciousness is, but a number of theorists have proposed that it may be related to working memory, a serially organized mental workspace where things can be compared and contrasted and mentally manipulated (Baddeley, 1992). A variety of studies of humans and nonhuman primates point to the

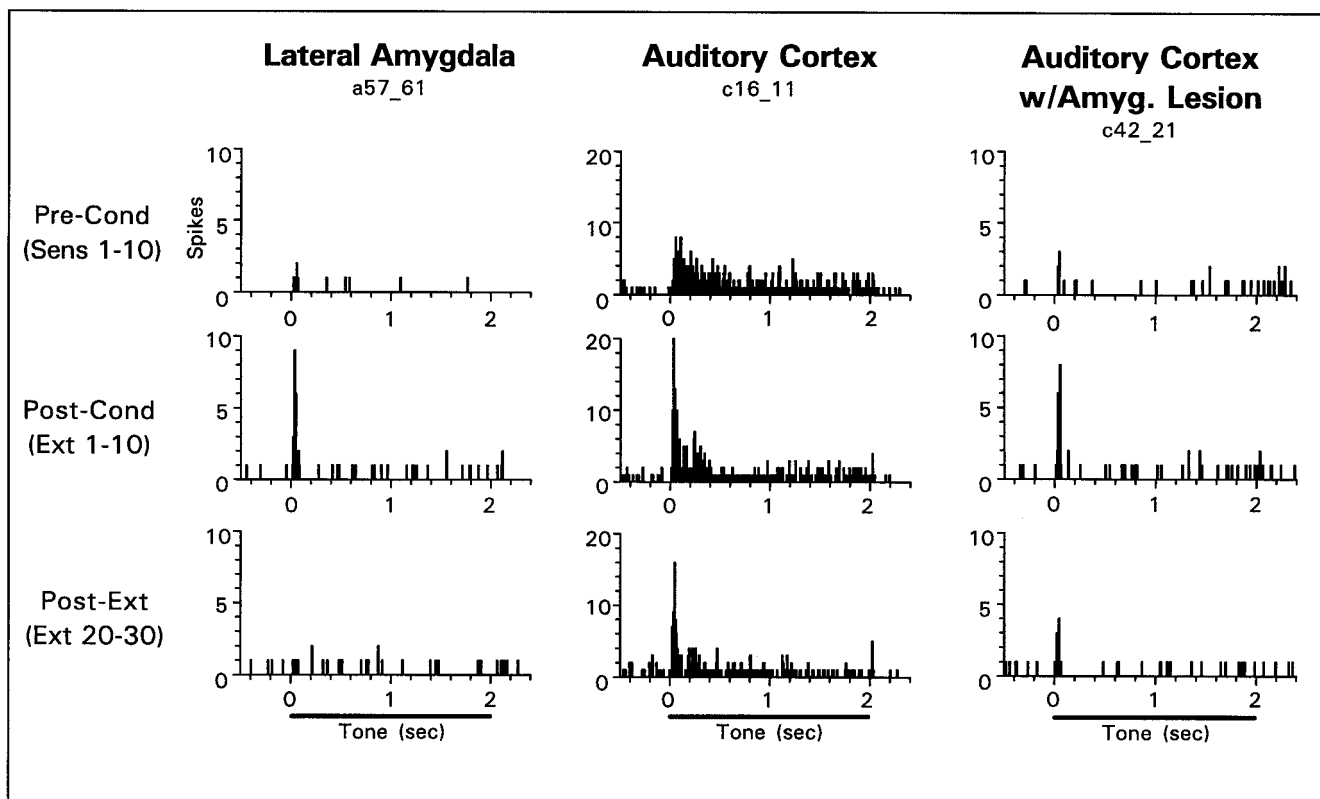

FIGURE 74.7 Poststimulus time histograms showing the effects of acquisition and extinction of onset tone responses in lateral amygdala, auditory cortex, and auditory cortex in animals with amygdala ablation. The auditory cortex cell from an intact rat developed onset-conditioned increases after conditioning (Post-Cond; extinction trials 1–10) that lasted through the entire extinction phase (Post-Ext; extinction trials 20–30).

In contrast, the amygdala cell and the auditory cortex cell of a lesioned animal developed short-latency conditioned increases that returned to preconditioning levels (Pre-Cond; sensitization trials 1–10) at the end of the extinction phase. Bin size 10 ms. (Adapted from Armony, Quirk, and LeDoux, 1998, and Quirk, Armony, and LeDoux, 1997.)

prefrontal cortex—especially the dorsolateral prefrontal areas, as well as the anterior cingulate and orbital cortical regions—as being involved in working memory (Goldman-Rakic, 1992). Immediately present stimuli and stored representations are integrated in working memory by way of interactions between prefrontal areas, sensory processing systems (which serve as short-term memory buffers, as well as perceptual processors), and the long-term explicit (declarative) memory system involving the hippocampus and related areas of the temporal lobe. In the case of an affectively charged stimulus, such as a trigger of fear, the same sorts of processes will be called upon as for stimuli without emotional implications, but in addition, working memory will become aware of the fact that the fear system of the brain has been activated. This additional information, when added to perceptual and mnemonic information about the object or event, could be the condition for the subjective experience of an emotional state of fear.

But what is the additional information that is added to working memory when the fear system is activated?

The amygdala projects to many cortical areas, even some that it does not receive inputs from (Amaral et al., 1992). It can thus influence the operation of perceptual and short-term memory processes, as well as processes in higher order areas. Although the amygdala does not have extensive connections with the dorsolateral prefrontal cortex, it does communicate with the anterior cingulate and orbital cortex, two other components of the working-memory network. But in addition, the amygdala projects to nonspecific systems involved in the regulation of cortical arousal. And the amygdala controls bodily responses (behavioral, autonomic, endocrine), which then provide feedback that can influence cortical processing indirectly. Thus working memory receives a greater number of inputs and receives inputs of a greater variety in the presence of an emotional stimulus than in the presence of other stimuli. These extra inputs may just be what is required to add affective charge to working-memory representations, and thus to turn subjective experiences into emotional experiences.

Modulation of Memory Storage by Stress Hormones and the Amygdaloid Complex

JAMES L. MCGAUGH, BENNO ROOZENDAAL, AND LARRY CAHILL

ABSTRACT It is well established that emotional arousal influences long-term explicit/declarative memory formation. The hypothesis guiding the research reviewed in this chapter is that this influence is mediated by activation of the amygdala by adrenergic and glucocorticoid stress hormones and that amygdala activation regulates memory consolidation occurring in other brain regions. This hypothesis is strongly supported by evidence that lesions of the amygdala block adrenal hormone influences on memory storage as well as evidence that drugs affecting adrenergic and glucocorticoid receptors modulate memory storage when infused directly into the amygdala after training. The memory-modulatory influences involve β -adrenergic activation in the basolateral nucleus of the amygdala. Other findings indicate that an intact amygdala is not required for expression of retention of memory influenced by amygdala activation. Findings of studies with human subjects confirm those of animal studies. Beta-adrenoceptor antagonists and lesions of the amygdala block the enhancing effects of emotional arousal on memory. Furthermore, long-term retention of emotional material is highly correlated with PET activation of the amygdala during learning. Such findings provide strong support for the hypothesis that the basolateral amygdala is part of a system that regulates the strength of explicit/declarative memories in relation to their emotional significance.

We remember most of the events in our lives rather poorly, and many of our experiences may be completely forgotten. However, memories for many experiences endure vividly. It has long been noted that emotionally arousing experiences are often the ones that are better remembered (James, 1890). Findings of studies in humans and animals provide compelling evidence that emotional experiences tend to be well remembered (Christianson, 1992). Significant personal experiences such as birthdays, weddings, special achievements, and awards tend to leave lasting memories. Studies investigating this issue report that people tend to remember rather well where they were and what they were doing when they experienced an earthquake (Neisser et al., 1996), witnessed an accident (Stratton, 1919; Bohannon, 1988), or learned surprising and important information

(Conway et al., 1994). Rats remember where they were in an apparatus when they received a foot shock (Vazdarjanova and McGaugh, 1998). Unpleasant and shocking experiences are not the only ones that are well remembered. Winners of Nobel Prizes, Academy Awards, and lotteries no doubt remember when and where they learned of the award. Such observational, experimental, and anecdotal evidence strongly suggests that emotional responses elicited by arousing experiences influence the storage of long-term memory of the events. That is, emotional arousal appears to play a central role in enabling the significance of events to influence the strength of the memories of events (McGaugh, 1992). Through this selective and highly adaptive influence, memories of exciting experiences generally endure while those of little significance are generally weakly retained unless, of course, they are strengthened by repetition (Ebbinghaus, 1885).

This chapter reviews research investigating the neurobiological systems mediating the influence of emotional arousal on long-term memory for events. That is, our focus is primarily on emotionally influenced storage of lasting explicit (episodic/declarative) memory. Emotional experiences also create learned emotional responses (Schlosberg, 1934; Mowrer, 1947; Davis, 1992; LeDoux, 1995). The findings of our experiments emphasize the importance of distinguishing between these two mnemonic consequences of emotional arousal.

In an early effort to offer a neurobiological account of the influence of emotional arousal on memory, Livingston (1967) suggested that stimulation of the limbic system and brainstem reticular formation might promote the storage of recently activated brain events by initiating a "neurohormonal influence [favoring] future repetitions of the same neural activities" (p. 576). Kety (1972) subsequently offered the more specific suggestion that adrenergic catecholamines released in emotional states may serve "to reinforce and consolidate new and significant sensory patterns in the neocortex" (p. 73).

Although the specific details of our findings and theoretical interpretations differ in many ways from those early views offered by Livingston and Kety, they are

JAMES L. MCGAUGH, BENNO ROOZENDAAL, and LARRY CAHILL Center for the Neurobiology of Learning and Memory and Department of Neurobiology and Behavior, University of California, Irvine, Calif.

consistent with their general hypotheses. Our findings indicate that stress-induced release of hormones from the adrenal medulla (epinephrine) and adrenal cortex (corticosterone in the rat) influence memory by activating noradrenergic systems projecting to the amygdala. The basic hypothesis that is suggested by these findings and that guides our current research is that emotionally arousing stimulation activates the amygdala, and that amygdala activity regulates the consolidation of long-term explicit memory of events by modulating neuroplasticity in other brain regions (McGaugh, Cahill, and Roozendaal, 1996; Cahill and McGaugh, 1998). That is, the amygdala is part of a system that serves to regulate the strength of memories in relation to their emotional significance. Furthermore, according to this view, the amygdala is not critically involved in the retrieval or behavioral expression of emotionally influenced explicit memory. This hypothesis is based on evidence from our studies examining the involvement of the amygdala in mediating stress hormone and drug influences on memory as well as studies of the effects of lesions and temporary inactivation of the amygdala. Although the conclusions are based primarily on findings of studies using rats, the conclusions are also supported by recent findings from studies using human subjects (Cahill, 1996).

Modulation of memory storage

Memory is, of course, inferred from changes in behavior; it is not directly observed. Experiments investigating the neural bases of learning and memory use many kinds of treatments, including lesions and drugs, that can and do directly affect behavior that is observed and used to make inferences about memory. Thus it is of critical importance to be able to distinguish the effects of the treatments on the inferred process of memory from the effects of the treatments on attentional, motivational, and motoric processes affecting the behavior used to assess memory.

The use of posttraining treatments to alter the brain functions shortly after training has provided an effective technique for dealing with this issue (McGaugh, 1966, 1989a; McGaugh and Herz, 1972). With the use of this paradigm brain functioning is experimentally altered only after learning has occurred, and with most treatments used the acute effects of the treatments are short-lasting and do not directly affect brain functioning when retention is tested a day or longer after the learning. This approach is based on the "consolidation hypothesis" originally proposed by Mueller and Pilzecker a century ago (1900) suggesting that memory traces are initially fragile and become consolidated over time. The consoli-

dation hypothesis has been strongly supported by extensive evidence from experimental as well as clinical findings (McGaugh and Herz, 1972; Weingartner and Parker, 1984). More importantly for the issues addressed in this chapter were the early findings that posttraining injections of stimulant drugs enhance memory when administered shortly after training (Breen and McGaugh, 1961; McGaugh, 1966, 1968, 1973) and are generally ineffective when administered several hours after learning (McGaugh and Herz, 1972). Such findings indicate that the drugs affect memory by modulating the consolidation of recently acquired information.

Hormonal modulation of memory storage

The susceptibility of memory storage processes to modulating influences induced after learning provides the opportunity for emotional activation to regulate the strength of memory traces representing important experiences (Gold and McGaugh, 1975; McGaugh, 1983a,b; McGaugh and Gold, 1989). It is well established that, in rats and mice, hormones of the adrenal medulla and adrenal cortex are released during and immediately after stressful stimulation of the kinds used in aversively motivated learning tasks (McCarty and Gold, 1981; McGaugh and Gold, 1989). Removal of adrenal hormones by adrenalectomy generally results in memory impairment (Borrell et al., 1983; Borrell, de Kloet, and Bohus, 1984; Oitzl and de Kloet, 1992; Roozendaal, Portillo-Marquez, and McGaugh, 1996).

EPINEPHRINE Gold and van Buskirk (1975) were the first to report that, in adrenally intact rats, systemic post-training injections of the adrenomedullary hormone epinephrine enhances long-term retention of inhibitory avoidance. As with stimulant drugs, the epinephrine effects were dose dependent and time dependent: Memory enhancement was greatest when the injections were administered shortly after training. Highly comparable effects have been obtained in experiments using many different types of training tasks, including inhibitory avoidance, active avoidance, discrimination learning, and appetitively motivated tasks (Introvini-Collison and McGaugh, 1986; Izquierdo and Diaz, 1985; Liang, Juler, and McGaugh, 1986; Sternberg et al., 1985). Thus the epinephrine effects on memory do not depend upon any specific task or motivational requirements. The evidence strongly supports the view that epinephrine enhances consolidation of the memory of the training experience.

GLUCOCORTICOIDS There is also extensive evidence that adrenocortical hormones are involved in modulat-

ing memory storage (for reviews see Bohus, 1994; de Kloet, 1991; Lupien and McEwen, 1997; McEwen and Sapolsky, 1995). As with epinephrine, single injections of moderate doses of glucocorticoids can enhance memory storage (Cottrell and Nakajima, 1977; Roozendaal and McGaugh, 1996a; Sandi and Rose, 1994). Because glucocorticoids are highly lipophilic, they readily enter the brain and bind directly to mineralocorticoid receptors (type I) and glucocorticoid receptors (type II) (McEwen, Weiss, and Schwartz, 1966; de Kloet, 1991). These two receptor types differ in their affinity for corticosterone and synthetic ligands. Mineralocorticoid receptors have a high affinity for the natural steroids corticosterone and aldosterone, whereas glucocorticoid receptors have a high affinity for synthetic ligands such as dexamethasone and RU 28362 (Reul and de Kloet, 1985; Reul et al., 1990; Sutanto and de Kloet, 1987). As a consequence, mineralocorticoid receptors are almost saturated during basal levels of corticosterone, whereas glucocorticoid receptors become occupied only during stress and at the circadian peak. Several findings suggest that the memory-modulating effects of glucocorticoids selectively involve activation of glucocorticoid receptors (Lupien and McEwen, 1997; Oitzl and de Kloet, 1992; Roozendaal, Portillo-Marquez, and McGaugh, 1996). Blockade of glucocorticoid receptors, but not mineralocorticoid receptors, shortly before or immediately after training impairs memory. Such findings strongly implicate the involvement of glucocorticoid receptors in memory storage and support the hypothesis that endogenously released glucocorticoids enhance memory storage.

ADRENERGIC-GLUCOCORTICOID INTERACTION Other findings indicate that catecholamines and glucocorticoids interact in influencing memory storage. Borrell and colleagues reported that glucocorticoids alter the sensitivity of epinephrine in influencing memory storage in adrenalectomized rats (Borrell et al., 1983; Borrell, de Kloet, and Bohus, 1984). We examined glucocorticoid-adrenergic interactions on memory storage in adrenally intact rats injected with metyrapone, a drug that reduces the elevation of circulating corticosterone induced by aversive stimulation (Roozendaal, Carmi, and McGaugh, 1996). Rats received systemic injections of metyrapone or a control solution 90 minutes before training in an inhibitory avoidance task and posttraining injections of epinephrine, amphetamine, or 4-OH amphetamine (a peripherally acting derivative of amphetamine). Both amphetamine drugs are known to stimulate the release of epinephrine from the adrenal medulla (Weiner, 1985). As shown in figure 75.1, all three adrenergic drugs enhanced retention. Metyrapone

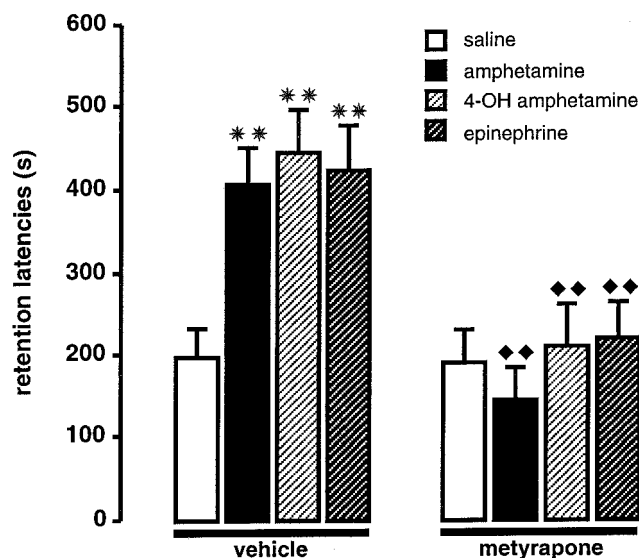

FIGURE 75.1 Step-through latencies (mean \pm SEM) for a 48-hour inhibitory avoidance test. Effects of corticosteroid synthesis blockade with metyrapone (50 mg/kg) on the enhancement of memory produced by posttraining injections of amphetamine (1.0 mg/kg), 4-OH amphetamine (2.0 mg/kg), or epinephrine (0.1 mg/kg). *** $p < .01$ as compared with the corresponding saline group; ◆◆ $p < .01$ as compared with the corresponding vehicle pretreatment group. (From Roozendaal, Carmi, and McGaugh, 1996.)

administration alone did not affect memory but completely blocked the memory-enhancing effects of the other three drugs. These findings indicate that stress-induced increases in plasma corticosterone and consequent activation of central glucocorticoid receptors are essential for enabling the memory-enhancing effects of epinephrine and amphetamine.

Amygdala involvement in neuromodulatory influences on memory consolidation

Extensive evidence indicates that epinephrine and glucocorticoid effects on memory are mediated by influences involving the amygdala. As epinephrine does not readily cross the blood-brain barrier, if at all, its influence on the amygdala *must* be mediated indirectly (Weil-Malherbe, Axelrod, and Tomchick, 1959). In contrast, it is well established that glucocorticoids readily enter the brain and bind directly to adrenal steroid receptors. Although these hormones differ in the way in which they influence the amygdala, they have remarkably similar effects on processes regulating memory consolidation. As will be discussed subsequently, activation of norepinephrine (NE) release in the amygdala appears to be an essential step in mediating the effects of peripheral catecholamines as well as those of glucocorticoids on memory storage.

ADRENERGIC INFLUENCES Our interest in the amygdala as a brain site mediating epinephrine effects on memory was guided by evidence that, in rats given inhibitory or active avoidance training, memory storage is modulated by electrical stimulation of the amygdala (McGaugh and Gold, 1976). Furthermore, adrenal demedullation and injections of epinephrine alter the memory-modulating effects of electrical stimulation of the amygdala (Liang, Bennett, and McGaugh, 1985). Additionally, lesions of either the amygdala or the stria terminalis, a major amygdala pathway, block epinephrine effects on memory storage (Cahill and McGaugh, 1991; Liang and McGaugh, 1983). Stria terminalis lesions alone do not block inhibitory avoidance performance, and amygdala lesions impair but do not block the learning (Liang and McGaugh, 1983; Cahill and McGaugh, 1990).

Posttraining intra-amygdala infusions of the β -adrenoceptor antagonist propranolol also block epinephrine effects on memory storage (Liang, Juler, and McGaugh, 1986). Such findings suggest that NE release in the amygdala is involved in mediating epinephrine effects on memory. In support of this implication, we and others have found that posttraining infusions of NE or the β -adrenoceptor agonist clenbuterol into the amygdala produce dose-dependent enhancement of memory storage (Introini-Collison, Miyazaki, and McGaugh, 1991; Introini-Collison, Dalmaz, and McGaugh, 1996; Liang, Juler, and McGaugh, 1986; Liang, McGaugh, and Yao, 1990; Liang, Chen, and Huang, 1995). Furthermore, posttraining intra-amygdala infusions of β -adrenoceptor antagonists impair retention and block the memory-enhancing effects of NE (Liang, Juler, and McGaugh, 1986; Liang, Chen, and Huang, 1995; Salinas et al., 1997).

Epinephrine effects on memory are also blocked by peripherally administered propranolol (Introini-Collison et al., 1992), a drug that readily enters the brain, as well as by sotalol, a β -adrenoceptor antagonist that does not readily enter the brain. The memory-modulating effects of other β -adrenoceptor agonists that enter the brain, including dipivefrin (DPE) and clenbuterol, are blocked by propranolol but not by sotalol (Introini-Collison et al., 1992). These findings, considered together with other evidence, suggest that epinephrine effects on memory storage are initiated by activation of peripheral β -adrenoceptor receptors located on vagal afferents (Schreurs, Seelig, and Schulman, 1986) that project to the nucleus of the solitary tract and that projections from the nucleus of the solitary tract release NE within the amygdala (Ricardo and Koh, 1978). Consistent with this hypothesis, inactivation of the nucleus of the solitary tract with lidocaine blocks epinephrine effects on memory (Will-

FIGURE 75.2 Effects of low- and high-intensity foot shock on norepinephrine (NE) release in the amygdala assessed by in vivo microdialysis and HPLC. NE levels are represented as mean (\pm SEM) of basal levels prior to foot shock. * $p < .05$; ** $p < .01$ as compared with the no-foot-shock group. (From Quirarte et al., 1998.)

iams and McGaugh, 1993). Additionally, other investigators have found that memory is enhanced in an “inverted-U” manner by posttraining electrical stimulation of vagal afferents (Clark et al., 1995). These findings thus provide strong support for the hypothesis that epinephrine effects on memory storage are mediated by the amygdala and that the effects involve activation of the release of NE within the amygdala.

A major implication of this hypothesis is that stimulation comparable to that used in inhibitory avoidance training should induce the release of NE in the amygdala. In experiments using in vivo microdialysis and high-performance liquid chromatography (HPLC), we found that foot-shock stimulation of the kind typically used in inhibitory avoidance training induced NE release within the amygdala (Galvez, Mesches, and McGaugh, 1996). As is shown in figure 75.2, NE release in the amygdala following foot-shock stimulation varied with the intensity of stimulation: Low-intensity foot-shock stimulation (0.30 mA for 3 seconds) induced a 41% increase in NE release, whereas a high-intensity foot shock (1.20 mA for 3 seconds) induced a 96% increase (Quirarte et al., 1998). NE release returned to baseline levels 30 minutes after foot shock. Furthermore, NE release in the amygdala is influenced by hormones known to modulate memory storage. Peripheral injections of epinephrine (Williams et al., 1998) or the opiate antagonist naloxone potentiate NE release induced by foot shock (Quirarte et al., 1998). This latter finding is consistent with evidence that intra-amygdala infusions of β -adrenergic antagonists block naloxone effects on memory storage (Introini-Collison, Nagahara,

and McGaugh, 1989; McGaugh, Introini-Collison, and Nagahara, 1988) as well as evidence that opiate agonists inhibit the release of NE in the brain (Arbilla and Langer, 1978).

GLUCOCORTICOID INFLUENCES Extensive evidence indicates that activation of adrenal steroid receptors in the hippocampus plays an important role in mediating the effects of glucocorticoids on memory (Bohus, 1994; McEwen and Sapolsky, 1995). Recent findings from our laboratory indicate that glucocorticoids also affect memory storage through influences involving the amygdala. The findings of our studies of the effects of glucocorticoids on memory for inhibitory avoidance training are similar to those of our studies of the effects of epinephrine. Lesions of the stria terminalis or amygdala block the memory-enhancing effects of post-training systemic injections of the synthetic glucocorticoid dexamethasone (Roozendaal and McGaugh, 1996a, 1996b). Furthermore, as will be discussed more extensively later, memory is modulated by intra-amygdala infusions of glucocorticoids (Roozendaal and McGaugh, 1997a), and these effects of glucocorticoids depend on noradrenergic activation in the amygdala.

INTERACTION OF NEUROMODULATORY SYSTEMS WITHIN THE AMYGDALA Activation of the noradrenergic system in the amygdala is also involved in mediating other neuromodulatory influences on memory, including those of opioid peptidergic and GABAergic systems. Posttraining systemic injections of opioid peptides and opiates generally impair memory, and as noted earlier, opiate antagonists enhance memory (Izquierdo and Diaz, 1983; McGaugh, 1989b; McGaugh, Introini-Collison, and Castellano, 1993). GABAergic antagonists and agonists enhance and impair retention, respectively (Brioni and McGaugh, 1988; Brioni, Nagahara, and McGaugh, 1989). Lesions of the amygdala or stria terminalis block opioid peptidergic and GABAergic influences on memory storage (McGaugh et al., 1986; Ammassari-Teule et al., 1991). Intra-amygdala infusions of propranolol block opiate and GABAergic influences on memory (McGaugh, Introini-Collison, and Nagahara, 1988; Introini-Collison, Nagahara, and McGaugh, 1989). In experiments using both inhibitory avoidance and water-maze spatial tasks, intra-amygdala infusions of the β -adrenoceptor agonist clenbuterol blocked the memory-impairing effects of β -endorphin administered concurrently. Moreover, low and otherwise ineffective doses of β -endorphin and propranolol-impaired memory when infused concurrently into the amygdala (Introini-Collison, Ford, and McGaugh, 1995).

Most of our experiments have used inhibitory avoidance training. But, as noted earlier, comparable effects have been obtained in experiments using other training tasks. A series of experiments examined the involvement of the amygdala in memory for a change in reward magnitude (CRM). In these experiments rats were first trained for several days to run in a straight alley for a large reward (10 pellets of food). The reward was then reduced to 1 pellet, and changes in running speeds (i.e., slower running) assessed the next day indicated memory of the decrease in reward (CRM). Post-training systemic administration of 4-OH amphetamine enhanced memory for CRM (Salinas, Williams, and McGaugh, 1996), and posttraining administration of the GABAergic agonist muscimol impaired memory for CRM (Salinas and McGaugh, 1995). Other findings indicate that, as with memory for other types of training, memory for CRM involves the amygdala. Posttraining intra-amygdala infusions of muscimol, lidocaine, or propranolol impaired memory for CRM (Salinas and McGaugh, 1995; Salinas, Packard, and McGaugh, 1993; Salinas et al., 1997). Additionally, posttraining intra-amygdala infusions of the GABAergic and agonist bicuculline enhanced memory for an *increase* in reward magnitude (Salinas and McGaugh, 1996). These latter findings, together with the findings that amygdala treatments affect spatial learning (e.g., Introini-Collison, Ford, and McGaugh, 1995), provide additional evidence strongly indicating that amygdala influences on memory storage are not restricted to the learning of aversive information. The neuromodulatory interactions found in our experiments are summarized schematically in figure 75.3. Additional glucocorticoid findings included in the figure are discussed in the next section.

Selective involvement of the basolateral nucleus of the amygdala

In the studies reviewed in the preceding section, the experiments involved lesions of the entire amygdaloid complex or intra-amygdala infusion volumes (0.5 or 1.0 μ l) that spread throughout the amygdala. Many experiments have suggested that two of the amygdala nuclei, the basolateral (BLA) and central (CEA), are involved in aversively based learning (Davis, 1992; LeDoux, 1995). However, the findings of a series of experiments (see table 75.1) indicate that the BLA is selectively involved in mediating neuromodulatory influences on memory storage. Our initial findings of the selective involvement of the BLA came from studies investigating the effects of benzodiazepines (BZDs) on memory. It is well established that BZDs impair memory when

FIGURE 75.3 Schematic summarizing the interactions of neuromodulatory influences on memory storage as suggested by the findings of our experiments.

administered before learning (Lister, 1985) and that BZDs affect memory for inhibitory avoidance through influences on GABAergic mechanisms in the amygdala (Izquierdo, Da Cunha, and Medina, 1990; Izquierdo et al., 1990). The BLA appears to be the critical amygdala nucleus mediating the memory impairment. We found that lesions restricted to the BLA blocked BZD effects on memory for inhibitory avoidance training, whereas lesions of the CEA were ineffective. In contrast, CEA lesions alone impaired retention, whereas BLA lesions did not (Tomaz, Dickinson-Anson, and McGaugh, 1992). Additionally, when BZDs were infused selectively into the BLA or CEA, only BLA infusions impaired memory (de Souza-Silva and Tomaz, 1995). Furthermore, posttraining intra-amygdala infusions of the BZD antagonist flumazenil enhanced memory when administered into the BLA, whereas infusions into the CEA were ineffective (Da Cunha et al., in press).

Experiments examining the effects of inactivation of amygdala nuclei with posttraining infusions of lidocaine provide additional evidence that the BLA is selectively involved in modulating memory storage. Infusions of lidocaine selectively infused into the BLA

immediately after inhibitory avoidance training impaired inhibitory avoidance retention, whereas infusions administered into the CEA were ineffective (Parent and McGaugh, 1994). Thus, although, as we have just noted (Tomaz, Dickinson-Anson, and McGaugh, 1992), an intact BLA is not essential for inhibitory avoidance acquisition and retention, disruption of the functioning of the BLA shortly after learning impairs memory. Noradrenergic influences on memory storage also selectively involve the BLA. As is shown in figure 75.4, the BLA is involved in modulating memory for spatial training in a water maze (Hatfield and McGaugh, 1999). Posttraining infusions of NE into the BLA enhanced spatial memory, whereas infusions of propranolol into the BLA impaired spatial memory.

The findings of several recent experiments indicate that glucocorticoid influences on memory storage also selectively involve the BLA and that the effects require noradrenergic activation within the BLA. As is shown in figure 75.5A, lesions of the amygdala restricted selectively to the BLA block the memory-enhancing effects of posttraining systemic injections of dexamethasone (Roozendaal and McGaugh, 1996a). Furthermore, as is shown in figure 75.5B, posttraining infusions of a specific glucocorticoid receptor agonist (RU 28362) selectively enhance retention when administered into the BLA (Roozendaal and McGaugh, 1997a). In addition to disrupting the memory-modulatory effects of a glucocorticoid in an inhibitory avoidance task, lesions of the BLA also block glucocorticoid effects on memory for water-maze spatial learning (Roozendaal, Portillo-Marquez, and McGaugh, 1996). Adrenalectomy 4–5 days prior to training impaired memory in this task, and immediate posttraining dexamethasone attenuated the adrenalectomy-induced memory impairment. Additionally, BLA lesions block the effect of adrenalectomy and glucocorticoids on retention. In contrast, lesions of the CEA impaired acquisition and retention performance but did not block the glucocorticoid-induced modulation of memory storage. These findings indicate that the effects of glucocorticoids on memory storage are mediated, at least in part, by binding directly to adrenal steroid receptors in the BLA. Furthermore, as we will discuss, the BLA appears to modulate the effects, on memory storage, of activation of adrenal steroid receptors in the hippocampus (Roozendaal and McGaugh, 1997b).

Other findings from our laboratory indicate that glucocorticoid influences on memory storage depend critically on β -adrenoceptor activation within the BLA. As is shown in figure 75.6, microinfusions of β -adrenoceptor antagonists administered into the BLA blocked

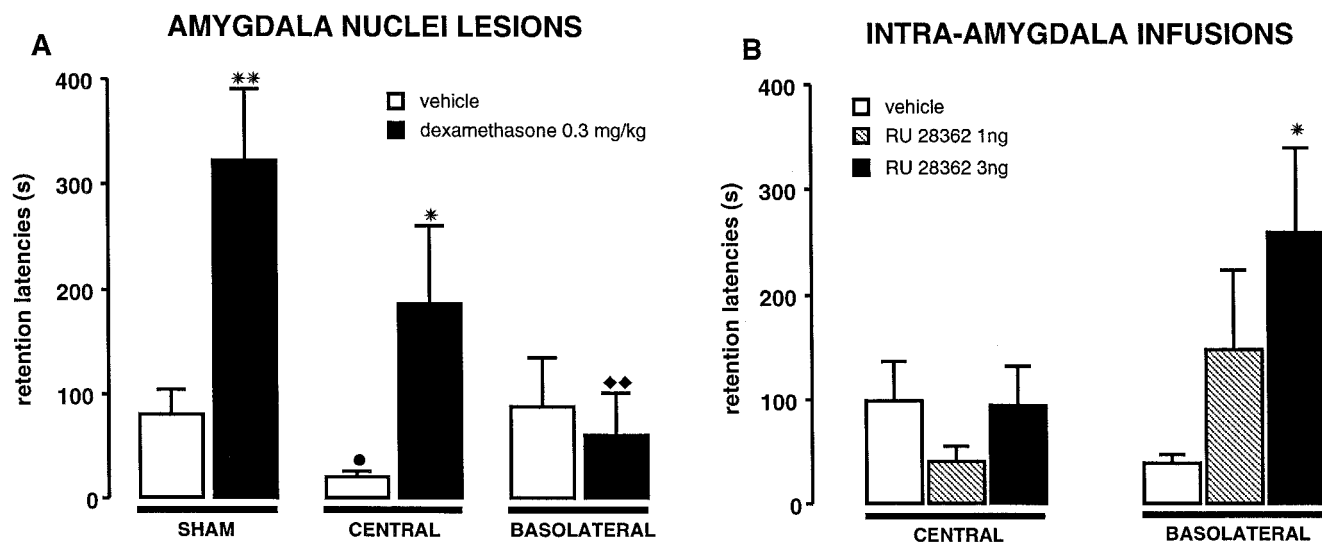

FIGURE 75.5 Step-through latencies (mean \pm SEM) on a 48-hour inhibitory avoidance test. the enhancing effects of posttraining systemic dexamethasone on inhibitory avoidance retention (Quirarte, Roozendaal, and McGaugh, 1997a). In contrast, β -adrenoceptor antagonist infusions administered into the CEA did not block dexamethasone effects on memory. Some of the effects can likely be explained by activation of glucocorticoid receptors in the ascending noradrenergic cell groups in the brain stem that are known to have high densities of glucocorticoid receptors (Harfstrand et al., 1986). As discussed earlier, noradrenergic projections from the nucleus of the solitary tract as well as the locus coeruleus activate the amygdala. In a recent study (Roozendaal, Williams, and McGaugh, 1999) we found that posttraining administration of the glucocorticoid receptor agonist RU 28362 into the nucleus of the solitary tract enhanced memory for inhibitory avoidance training. Moreover, this effect was blocked in animals given the β -adrenoceptor antagonist atenolol in the BLA. Other studies from our laboratory indicate that glucocorticoids may also interact with the noradrenergic system in the BLA in other ways. Recent findings suggest that the BLA is a locus of interaction between glucocorticoids and the noradrenergic system. As is shown in figure 75.7, blockade of glucocorticoid receptor in the BLA with the specific antagonist attenuated the dose-response memory-enhancing effect of the β -adrenoceptor agonist clenbuterol infused into the BLA posttraining (Quirarte, Roozendaal, and McGaugh, 1997b). Thus it appears that glucocorticoid receptor activation in the

BLA influences the effectiveness of β -adrenergic stimulation in modulating memory storage. Such a permissive role of glucocorticoids on the action of the noradrenergic system is consistent with findings of biochemical studies examining such interactions in hippocampal and cortical tissue (McEwen, 1987).

Amygdala interactions with other brain systems in modulating memory storage

The findings summarized in the previous section indicate that the amygdala is a site for integrating the interactions of neuromodulatory systems influencing memory storage and that the BLA is of critical importance. However, the findings do not reveal the brain sites at which amygdala activity modulates memory storage. Evidence from several kinds of studies has suggested that neural changes mediating fear conditioning may be located within the amygdala (Davis, 1992; LeDoux, 1995). Additionally, several studies have reported that long-term potentiation can be induced in the amygdala (Chapman et al., 1990; Clugnet and LeDoux, 1990; Maren and Fanselow, 1995; McKernan and Shinnick-Gallagher, 1997; Rogan, Stäubli, and LeDoux, 1997), and others have reported that drugs that block long-term potentiation also attenuate fear-based learning (Campeau, Miserendino, and Davis, 1992; Fanselow and Kim, 1994; Gewirtz and Davis, 1997; Kim and McGaugh, 1992). As yet, however, it cannot be concluded that long-term potentiation in the amygdala serves as a

FIGURE 75.6 Step-through latencies (mean \pm SEM) for a 48-hour inhibitory avoidance test. Effects of pretraining infusions of either the nonspecific β -adrenoceptor antagonist propranolol (0.5 μ g in 0.2 μ l), the β_1 -adrenoceptor antagonist atenolol (0.5 μ g in 0.2 μ l), or the β_2 -adrenoceptor antagonist zinterol (0.5 μ g in 0.2 μ l) into the basolateral or central amygdala and immediate posttraining subcutaneous injections of dexamethasone (0.3 mg/kg). * $p < .05$; ** $p < .01$ as compared with the corresponding vehicle group; ♦♦ $p < .01$ as compared with the corresponding saline-dexamethasone group. (From Quirarte, Roozendaal, and McGaugh, 1997a.)

basis for fear-based memory (Stevens, 1998). Further, it is clear that amygdala involvement in memory is not restricted to effects involving fear conditioning. The amygdala is involved in mediating appetitive as well as aversive learning (Burns, Everitt, and Robbins, 1994). Additionally, as we have emphasized, there is extensive evidence that alteration of amygdala functioning influences memory for training involving different motivation as well as different kinds of learned information

FIGURE 75.7 Step-through latencies (mean \pm SEM) for a 48-hour inhibitory avoidance test. Effects of pretraining infusions of the specific glucocorticoid receptor antagonist RU 38486 (1.0 ng in 0.2 μ l) into the basolateral amygdala and immediate posttraining infusions of the β -adrenoceptor agonist clenbuterol (1, 10, or 100 ng in 0.2 μ l) into the BLA. ** $p < .01$ as compared with the corresponding saline group; ♦♦ $p < .01$ as compared with the corresponding vehicle-clenbuterol group. (From Quirarte, Roozendaal, and McGaugh, 1997b.)

(Burns, Everitt, and Robbins, 1994; Hatfield and Gallagher, 1995; Hatfield and McGaugh, 1999; Killcross, Robbins, and Everitt, 1997; McGaugh, Introini-Collison, and Nagahara, 1988; Salinas and McGaugh, 1996).

Other evidence strongly suggests that the amygdala is not a site of memory storage for the information acquired in the tasks typically used in our experiments, including inhibitory avoidance and water-maze spatial tasks. Lesions of the amygdala (Parent, Tomaz, and McGaugh, 1992; Parent, West, and McGaugh, 1994) or BLA (Parent and McGaugh, 1994; Parent, Avila, and McGaugh, 1995) induced one week or even one month after aversive training do not block inhibitory avoidance retention performance. Additionally, large lesions of the amygdaloid complex induced before training typically attenuate but do not block inhibitory avoidance retention performance (Cahill and McGaugh, 1990). Further, although amygdala lesions typically impair the expression of conditioned fear as assessed by fear-potentiated startle (Davis, 1992) or "freezing" behavior (LeDoux, 1995), overtraining of fear conditioning attenuates the freezing deficit (Maren, 1998) and enables reacquisition of fear-potentiated startle (Kim and Davis, 1993). Such findings clearly demonstrate that an intact amygdaloid complex is not essential for the acquisition and expression of fear conditioning.

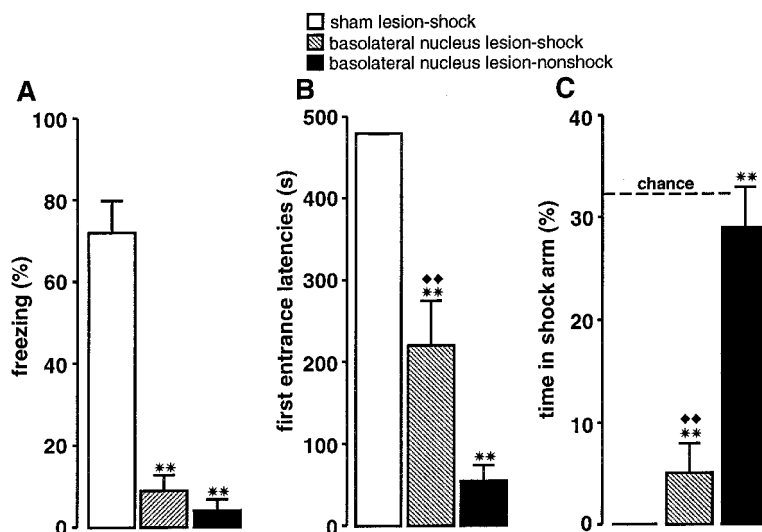

FIGURE 75.8 Effects of basolateral amygdala lesions on several measures of retention 24 hours after context foot-shock pairing in a three-arm maze. (A) Percent total time (mean \pm SEM) rats spent in freezing behavior. (B) First entrance latency (mean \pm SEM) to enter the former shock arm. (C) Percent total time (mean \pm SEM) rats spent in the former shock arm. The

dotted line depicts the level of chance. ** $p < .01$ as compared with the sham-lesion-shock group; ♦♦ $p < .01$ as compared between the basolateral nucleus lesion-nonshock and basolateral nucleus lesion-shock groups. (From Vazdarjanova and McGaugh, 1998.)

In such experiments it is, of course, essential to distinguish the effects of the lesions on performance of the response used as an index of fear from effects on learning of the significance of the cues inducing the fear. This issue can be addressed by using different behavioral measures to make inferences about learned fear. In a recent experiment in our laboratory (Vazdarjanova and McGaugh, 1998), BLA-lesioned and sham-lesioned control rats were given a series of foot shocks in one alley of a Y-maze. Other animals did not receive foot shocks. For retention testing 24 hours later the rats were placed in one of the other alleys, and several measures of behavior were recorded for 8 minutes (see figure 75.8). In comparison with the sham-lesioned controls, the lesioned rats displayed less “freezing” and entered the “shock” alley more quickly (i.e., were impaired in inhibitory avoidance). Additionally, and most importantly, in comparison with animals not given foot shock, the lesioned rats given foot shock, like the sham-lesioned controls, spent significantly less time in the alley where they had previously received foot shocks. Thus measures based on locomotor activity suggested that the behavior used to assess memory of the foot-shock training was blocked (freezing) or impaired (inhibitory avoidance) in the BLA-lesioned rats. However, it was clear that rats with BLA lesions, like nonlesioned controls, remembered the place in the maze where they had received the foot-shock stimulation. These findings indicate that an intact BLA is not required for expressing explicit/declarative memory of learned fear. Additionally, the findings em-

phasize the importance of using a variety of behavioral observations that enable assessment of memory for aversive stimulation.

Studies measuring conditioned neuroendocrine responses provide additional evidence that the amygdala is not a long-term site of memory for fear conditioning (Roozendaal, Koolhaas, and Bohus, 1992). In agreement with findings of others, lesions of the amygdala induced one day after training blocked rats’ freezing behavior. However, conditioned neuroendocrine responses remained intact. Moreover, studies using strains of rats that differ in their tendencies to freeze in response to fearful stimulation indicated that, in both strains, post-training intra-amygdala infusions of NE enhanced memory of an aversive event (mild shock delivered through a probe inserted into the cage). However, the expression of the enhanced memory depended on the rats’ ability to freeze. In the strain of rats that normally displayed freezing, the posttraining NE enhanced freezing. In the other strain the posttraining NE did not enhance freezing but, instead, enhanced another natural defensive response (i.e., burying and biting of the probe) typically displayed by rats of this strain. Such findings indicate that amygdala NE has a comparable role in regulating memory storage for fear conditioning and inhibitory avoidance learning (Roozendaal, Koolhaas, and Bohus, 1993).

Findings of other recent experiments provide additional evidence suggesting that the lateral/basolateral nuclei have time-limited roles in modulating memory

storage. Hess and colleagues (1997) examined c-fos expression induced by olfactory discrimination training and retention testing and found that c-fos in the BLA was selectively activated by the training. Quirk, Armony, and LeDoux (1997) recorded unit activity in the lateral amygdala and auditory cortex of rats given fear conditioning and extinction and reported that conditioned changes in cell firing in the auditory cortex generally occurred after changes in the amygdala. Furthermore, amygdala units extinguished relatively rapidly, whereas the cortical units persisted in responding during the extinction. A recent study (LaBar et al., 1998), using fMRI brain imaging to study changes induced by classical fear conditioning in human subjects, reported findings indicating a time-limited role for the amygdala for such learning. These findings suggested, "The amygdala, therefore, may preferentially signal the detection of affective signals when they are novel, or in the initial stages of learning when their emotional meaning is actively encoded" (LaBar et al., 1998, p. 940). Another study using fMRI to study brain changes induced by classical fear conditioning in humans (Buchel et al., 1998) reported finding habituation in the lateral amygdala nucleus during continued activation of cortical areas and concluded that "these observations suggest that with time, mnemonic representations of behaviorally salient contexts are expressed in *cortical* regions other than medial temporal lobe structures" (p. 954). Collectively, these findings provide additional support for our view that the amygdala has a temporally limited role in modulating memory storage occurring elsewhere in the brain (Cahill and McGaugh, 1998; McGaugh et al., 1984; McGaugh, 1989c; McGaugh, Cahill, and Roozendaal, 1996; Packard et al., 1995).

The findings of several experiments provide additional evidence that the amygdala is involved in regulating memory consolidation occurring in other brain regions. The amygdala sends efferent projections to many brain regions including direct projections to the striatum via the stria terminalis. Additionally, the finding that *N*-methyl-D-aspartate infused into the amygdala induces the expression of the proto-oncogene c-fos in the dentate gyrus of the dorsal hippocampus and the caudate nucleus indicates that the amygdala is functionally connected with both of these brain structures (Packard et al., 1995).

There is considerable evidence based on "double-dissociation" studies indicating that the caudate nucleus and hippocampus are involved in mediating different forms of memory (Packard and McGaugh, 1992, 1996). Hippocampal lesions selectively impair water-maze spatial learning (swimming to a submerged platform) (Morris et al., 1982; Moser, Moser, and Anderson, 1993; Olton,

Becker, and Handelman, 1979), whereas caudate lesions selectively impair water-maze visually cued learning (swimming to a visible platform) (Packard and McGaugh, 1992). The findings of several recent experiments indicate that the amygdala modulates memory storage for both hippocampal-dependent and caudate nucleus-dependent learning tasks (Packard, Cahill, and McGaugh, 1994; Packard and Teather, 1998). As is shown in table 75.2, unilateral posttraining infusions of amphetamine administered into the dorsal hippocampus immediately after a single training session enhanced memory storage for the spatial version of the water maze but not for the cued version, whereas amphetamine infused into the caudate nucleus after training enhanced memory for the cued but not the spatial task. However, amphetamine injected into the amygdala posttraining enhanced memory storage for both the spatial and the cued versions of the task. These findings clearly indicate that activation of the amygdala modulates memory storage processes for both hippocampal-dependent and caudate nucleus-dependent tasks. Additionally, inactivation of the amygdala prior to the retention tests did not block the enhanced retention induced by the posttraining intra-amygdala infusions of amphetamine (Packard, Cahill, and McGaugh, 1994). In other experiments examining the memory-enhancing effects of posttraining intra-amygdala infusions of amphetamine (Packard and Teather, 1998), infusions of lidocaine into the hippocampus prior to retention testing selectively blocked the memory enhancement obtained in the spatial task, whereas infusions of lidocaine into the caudate selectively blocked the enhanced memory for cued training. And, as was found in the earlier experiment (Packard, Cahill, and McGaugh, 1994), lidocaine infused into the amygdala prior to the retention test did not block amphetamine-induced memory enhancement in either task. The finding that an intact amygdala is not required for the expression of retention of either the spatial or the cued learning provides further evidence that the learning is not mediated by lasting neural changes located within the amygdala.

Other recent findings indicate that inputs from the BLA play a role in enabling the processing of hippocampally dependent memory (Roozendaal, Sapolsky, and McGaugh, 1998). Posttraining intrahippocampal administration of a glucocorticoid receptor agonist enhanced retention of inhibitory avoidance training. However, the memory enhancement was completely blocked in animals with BLA lesions. Lesions of the CEA were ineffective (Roozendaal and McGaugh, 1997b). Consistent with other studies indicating the importance of the BLA noradrenergic system in memory storage modulation, antagonism of β -adrenoceptors in the BLA with atenolol also

blocked the memory-enhancing effects of glucocorticoid administration into the hippocampus. (Roozendaal et al., 1998).

These findings are of interest in relation to evidence indicating that selective lesions of the BLA, but not the CEA, attenuate the induction of long-term potentiation in the dentate gyrus in vivo (Ikegaya, Saito, and Abe, 1994, 1995a). A β -adrenoceptor antagonist infused into the BLA also blocked dentate-gyrus long-term potentiation (Ikegaya et al., 1997). Moreover, high-frequency stimulation of the BLA facilitates the induction of long-term potentiation in the dentate gyrus (Ikegaya, Saito, and Abe, 1995b). Thus these physiological findings are consistent with findings of behavioral studies indicating that modulation of memory storage involves noradrenergic influences in the BLA and that the BLA influences memory by modulating memory storage in other brain structures. Another important feature of a recent study (Roozendaal et al., 1998) and those by Ikegaya and colleagues is that the effects of the glucocorticoid receptor agonist on memory as well as electrical stimulation of the hippocampus on long-term potentiation were blocked only by manipulation of the ipsilateral BLA. Lesions or pharmacological inhibition of the contralateral BLA were not effective in altering the hippocampal effects. Although at present it is not known precisely how the BLA affects hippocampal function, some evidence indicates an involvement of the BLA–nucleus accumbens pathway. The nucleus accumbens receives projections from both the BLA and hippocampus (O'Donnell and

Grace, 1995). As discussed previously, lesions of the stria terminalis, which carries the projections from the BLA to the nucleus accumbens, exert effects highly comparable to those induced by amygdala or selective BLA lesions. Moreover, excitotoxic lesions of the nucleus accumbens also block the memory-modulating effects of posttraining systemic injections of dexamethasone (Setlow, Roozendaal, and McGaugh, 1999).

Emotionally influenced memory storage in human subjects

Several recent studies of memory in human subjects provide additional evidence that drugs affecting adrenergic systems modulate memory storage and that the effects are mediated through influences involving the amygdala. As noted earlier, there is extensive evidence from animal experiments that posttraining systemic (or intra-amygdala) administration of amphetamine enhances memory storage. Consistent with those findings, Soetens and colleagues (Soetens, D’Hooge, and Huetting, 1993; Soetens et al., 1995) reported that administration of amphetamine to human subjects before or immediately after learning of word lists enhanced long-term retention of the words.

Other recent experiments examined the effects of β -adrenoceptor antagonists on memory in human subjects. One experiment (Cahill et al., 1994) examined in healthy volunteers the effect of the β -adrenoceptor antagonist propranolol or a placebo on long-term (i.e., 1-

² Packard and Teather (1998)

week) memory for either an emotionally neutral story or a closely matched but more emotionally arousing story. Propranolol selectively impaired memory for the emotionally arousing story. The memory impairment could not be attributed to effects on attention, sedation, or emotional reactions of the subjects during story viewing. Another recent study confirmed the impairing effect of propranolol on memory for the emotional story and found that nadolol (a β -adrenoceptor antagonist that does not easily cross the blood-brain barrier) did not affect memory for either the emotionally arousing or neutral story (van Stegeren et al., 1998). The lack of effect of nadolol on memory suggests that the impairing effect of propranolol in this situation likely results from central, rather than peripheral, actions of the drug. Last, Nielson and Jensen (1994) examined the effect of β -adrenoceptor antagonists on enhanced memory induced by physical arousal (i.e., increased muscle tension). The arousal did not enhance retention in elderly subjects who were taking beta-blockers as medication. These experiments are consistent with extensive findings of animal studies indicating that modulation of explicit or declarative memory storage by emotional arousal involves activation of β -adrenoceptors.

In addition to β -adrenoceptor activation, amygdala function is now implicated in enhanced memory for emotional material in humans. Experiments using the same general procedures used in the experiment by Cahill and colleagues (1994) indicate that emotional arousal does not enhance long-term declarative memory in humans with selective, bilateral amygdala lesions (Cahill et al., 1995; Adolphs et al., 1997). Interestingly, the reactions of amygdala-damaged subjects to the emotional material in these studies appeared normal, suggesting therefore that the amygdala in humans may not be as critical for the production of an emotional reaction per se as for processes translating an emotional reaction into enhanced long-term memory. It is of interest that, in contrast to findings seen in subjects with damaged amygdalae, amnesic subjects with intact amygdalae demonstrate normal enhancement of memory for emotional material (Hamann, Cahill, and Squire, 1997; Hamann et al., 1997).

The results of a recent PET scan study of memory in human subjects provide further evidence that the amygdala is involved in emotionally influenced memory (Cahill et al., 1996). Subjects viewed a series of brief, emotionally arousing videos and, in a second session, a series of relatively emotionally neutral videos. Three weeks later memory of the videos was assessed with a surprise free-recall test. As is shown in figure 75.9, glucose metabolic rate of the right amygdala induced by viewing the emotional film clips correlated highly ($+0.93$) with the number of films recalled. Amygdala activity did

FIGURE 75.9 Amygdala activity in humans correlated with the formation of memory for emotionally arousing information. Graph shows correlation between glucose utilization in the right amygdala of 8 healthy subjects while viewing a series of relatively emotionally arousing (negative) films and long-term (3-week) recall of those films. (From Cahill et al., 1996.)

not correlate significantly with subjects' self-assessed emotional reactions to viewing the films. Consistent with the findings from patients with amygdala damage, these PET findings suggest greater involvement of the human amygdala in the formation of long-term memory for emotionally arousing events than in the production of emotion per se.

Conclusions

Collectively, these studies of emotionally influenced memory in human subjects are clearly consistent with findings of animal experiments indicating that β -adrenoceptor receptor activation and the amygdala participate in the formation of long-term, explicit/declarative memory for emotional events. Our findings based on studies of memory in animal and human subjects are consistent with those from other laboratories indicating that adrenal stress hormones and the amygdala, especially the BLA, are involved in regulating the consolidation of emotionally influenced explicit/declarative memory. Noradrenergic activation within that nucleus appears to be critical. Our findings also indicate that an intact amygdala is not required for the expression of emotionally influenced explicit/declarative memory and suggest that the amygdala regulates memory consolidation processes by modulating neural plasticity in other brain regions. The findings provide strong support for the hypothesis that the BLA is part of a neuromodulatory system that regulates the strength of explicit/declarative memories in relation to their emotional significance.

76 Neurophysiological Basis of Emotion in Primates: Neuronal Responses in the Monkey Amygdala and Anterior Cingulate Cortex

TAKETOSHI ONO AND HISAO NISHIJO

ABSTRACT Both the amygdala and anterior cingulate cortex, which are main components of the rhinencephalon, have been implicated in emotion. Neuronal responses in the amygdala and anterior cingulate cortex of the monkey to stimuli that were considered to be biologically significant were studied in behavioral tasks that involved the discrimination of different rewarding and aversive stimuli. Neurons in the amygdala displayed modulation of responses to objects in various situations including satiation and reversal, and in a specific context in which food delivery was expected. This finding suggests that the amygdala is involved in ongoing evaluation of sensory stimuli in a context-relevant manner. However, our results suggest that the anterior cingulate cortex integrates inputs from other emotion-related regions and from the frontal cortex, and sends the information to motor executive centers to behave appropriately in a variety of specific motivational or emotional behavioral contexts. The present results could provide neuronal bases for the involvement of these emotion-related areas in human emotional and motivated behaviors.

It has been reported that emotional responses are highly dependent on cognitive factors (Hebb, 1972). Extensive studies using Pavlovian conditioning indicate that animals such as rodents can well localize a relevant simple stimulus in the environment and display emotional responses to such a stimulus (i.e., conditioned emotional response). In higher mammals such as monkeys, a wider variety of complex stimuli can be recognized by the sophisticated cortical sensory systems. In turn, this ability enables higher mammals to display emotional responses to a wider variety of complex stimuli such as "death masks" to which rodents do not respond (Hebb, 1972). The amygdala (AM) and the anterior cingulate cortex (AC) as well as cortical sensory systems have been implicated in a variety of cognitive and emotional pro-

cesses, and their evolution and differentiation in mammals are parallel to the evolution of complex emotional and social behaviors (MacLean, 1986; Stephan, Frahm, and Baron, 1987). It has been suggested that sequential processing of sensory information occurs in the neocortex (Turner, Mishkin, and Knapp, 1980; Pons et al., 1987). The AM receives highly integrated sensory information from all modalities in a late stage of this sequential processing (Gloor, 1960; Aggleton, Burton, and Passingham, 1980; Turner, Mishkin, and Knapp, 1980; Amaral et al., 1992), and emotional and cognitive functions of the AM depend on such connections (Turner, Mishkin, and Knapp, 1980). The anterior part of area 24 (AC) receives inputs from the prefrontal cortex and the emotion-related areas including the AM as well as other association cortices (Vogt and Pandya, 1987).

Bilateral lesion of the temporal cortex including the AM produces Klüver-Bucy syndrome (Klüver and Bucy, 1939; Weiskrantz, 1956; Gloor, 1960). This syndrome consists of a complex set of several affective disorders: tameness; approach to normally fear-inducing stimuli such as humans, gloves, and bear models (loss of fear); increased and inappropriate sexual behavior (hypersexuality); and tendency to investigate orally and put inedible objects into mouth (oral tendency). Approach to aversive stimuli and deficits in discriminating food from nonfood are known as *psychic blindness*, which is an inability to identify the biological significance of stimuli. The AM is suggested to be a focal point of causes contributing to Klüver-Bucy syndrome (Gloor, 1960; Goddard, 1964). Electrical stimulation and unit recording as well as selective lesion studies also manifest the crucial role of the AM in emotional behavior (Kaada, 1972; Sanghera, Rolls, and Roper-Hall, 1979; Ono et al., 1980; LeDoux, 1987; Davis, 1992). However, animals with AM lesions had neither sensory deficits (Aggleton, 1992) nor deficits in executing motivated

TAKETOSHI ONO and HISAO NISHIJO Department of Physiology, Faculty of Medicine, Toyama Medical and Pharmaceutical University, Toyama, Japan

and emotional behaviors in response to unconditioned stimuli (i.e., primary reinforcement) (Gallagher, Graham, and Holland, 1990; Everitt, Cador, and Robbins, 1989; Everitt et al., 1991).

This evidence supports the idea that the AM is related to ongoing evaluation of the affective significance of learned conditioned sensory stimuli and of the learning processes that associate sensory stimuli with affective significance (stimulus-affect association) (Weiskrantz, 1956; Geschwind, 1965; Jones and Mishkin, 1972; Mishkin and Aggleton, 1981; Gaffan and Harrison, 1987; Nishijo, Ono, and Nishino, 1988a, 1988b; Cador, Robbins, and Everitt, 1989; Everitt, Cador, and Robbins, 1989; Everitt et al., 1991).

This conclusion leads to two important ways in which the AM is functionally significant. First, the amygdalotomized animals cannot appreciate the emotional significance of a stimulus, resulting in deficits in emotional expression due to inability to activate the executing systems for behavioral and autonomic responses. This function may depend on the sequential sensory pathway from sensory association cortices to the brainstem executive system including the hypothalamus for emotional expression through the AM. Second, the AM might contribute to plasticity of cortical neurons during learning through two pathways directed to the neocortex. One consists of the widespread direct cortical projections from the AM (Amaral and Price, 1984; Amaral et al., 1992), and the other, cholinergic projections to the neocortex by way of the substantia innominata, to which the AM projects (Russchen, Amaral, and Price, 1985). It has been reported that receptive fields of auditory-responsive neurons in the neocortex could be changed plastically by conditioned associative learning (Weinberger et al., 1990). Computational study suggested that this plasticity of receptive fields in the neocortex was attributed to neocortical inputs from a value-dependent learning system consisting of the AM and substantia innominata (Friston et al., 1994).

However, most works on the functional significance of the AC have been concerned with their role in "emotional activity" or responses to noxious stimuli (Papez, 1937; Vogt, David, and Olson, 1992). Papez (1937) viewed the cingulate cortex as the cortical receptive region for the experiencing of emotion and argued, "The cingulate cortex is the seat of dynamic vigilance by which environmental experiences are endowed with an emotional consciousness." Tumors of the cingulate cortex are known to produce apathy, drowsiness, memory defects, and stupor (Vogt, David, and Olson, 1992). Recent PET studies suggested that the obsessive-compulsive disorder of humans could be ascribed to hyperactivity of the AC (Sawle et al., 1991). Patients with

affective illness such as schizophrenics had abnormal GABA_A receptor binding in the AC (Benes et al., 1992). Activity and volume of the AC of depressive patients was decreased (Drevets et al., 1997). All of these relations suggest AC involvement in emotion and complex behavioral control.

In this chapter, we first characterize the responses of AM and AC neurons to affective sensory stimuli that are related to ongoing evaluation of the affective significance of the stimuli. Amygdala and AC neuronal responses to stimuli that were considered to be biologically significant (Weiskrantz, 1956; Horel, Keating, and Misantone, 1975; Perrett, Rolls, and Caan, 1982) were studied in various behavioral tasks that involved the discrimination of different rewarding and aversive stimuli (Ono et al., 1980; Fukuda, Ono, and Nakamura, 1987; Nishijo et al., 1986, 1997; Nishijo, Ono, and Nishino, 1988a, 1988b). Comparison of AM and AC neuronal responsiveness to affective sensory stimuli may elucidate differences in the functions of these two structures. To characterize AM neuronal responsiveness indicating AM involvement in stimulus-affect association, some AM neurons were further tested by changing the affective significance of the stimuli presented. Second, since both disconnection of sensory inputs to the AM and disconnection of outputs from the AM to the hypothalamus resulted in Klüver-Bucy syndrome (Downer, 1961; Hilton and Zbrozyna, 1963; Horel, Keating, and Misantone, 1975; Gaffan, Gaffan, and Harrison, 1988), effects of disconnection of AM inputs and outputs were investigated (Fukuda, Ono, and Nakamura, 1987). Functional connections between the association cortex and the AM, which may underlie AM responsiveness to complex sensory stimuli, were investigated by analyzing neuronal response changes during reversible disconnection of the inferotemporal cortex (ITCx) from the AM. Disconnection of the AM from the hypothalamus, which receives AM outputs, was also tested by cooling the AM during recording of lateral hypothalamic (LHA) neurons.

Amygdalar neuronal responses during visual discrimination

TASK PARADIGMS *Macaca fuscata* monkeys were restrained painlessly in a stereotaxic apparatus by a previously prepared, surgically fixed head holder designed in our laboratory (Ono et al., 1980; Ono, Nishino, et al., 1981). They sat in a chair facing a panel that had two shutters (one opaque and one transparent) and a bar for operant responding. Liquid was accessible to the monkey through a small spout controlled by an electromagnetic valve [figure 76.1A,a] (Nishijo,

FIGURE 76.1 Schema of experimental setups and task paradigms of original (A) and modified (B) versions. (A) Original version. (a) A monkey sat in a chair facing a panel with a bar, and a window covered by two shutters (W1, an opaque shutter; W2, a transparent shutter in front of a stage). Liquid was delivered from a spout near the monkey's mouth. (b) Time sequence of visual discrimination tasks that involved presentation of food or non-food objects (solid line), white and red cylinders associated with liquid (dashed line), and brown cylinder associated with avoidance (dashed line). Shutters opened at Up. BP: indications of individual bar presses and time during which they occurred. Liquid dispensed from spout after last bar press if a particular object was presented. (B) Modified version. (a) Schema of an ex-

perimental setup. The monkey could see an object through a one-way mirror (S1) in front of the stage when a light was turned on. However, another shutter (S2) prevented access to the bar. (b) Time sequence of visual discrimination task of the modified version. A trial was initiated by a warning tone (Tone). After a delay of at least 2 seconds, S2 was opened automatically. The S1 shutter was opened by the last bar press. The monkey's behavior and the neuronal responses were essentially the same in this and the previously described situation. The monkey can take a drop of juice dispensed from spout after the last bar press, or a cookie or raisin from the stage, which is made available by the opening of S1 after the last bar press; it can also avoid shock by bar pressing.

Ono, and Nishino, 1988a, 1988b). Aversive stimulation was administered as a weak electric shock applied between the earlobes. In the visual discrimination task an opaque shutter (W1) was opened at random intervals.

The monkey could see an object through a transparent shutter (W2) in front of the stage. The animal could then obtain the object if it wanted to, by pressing the bar a predetermined number of times (fixed ratio, FR

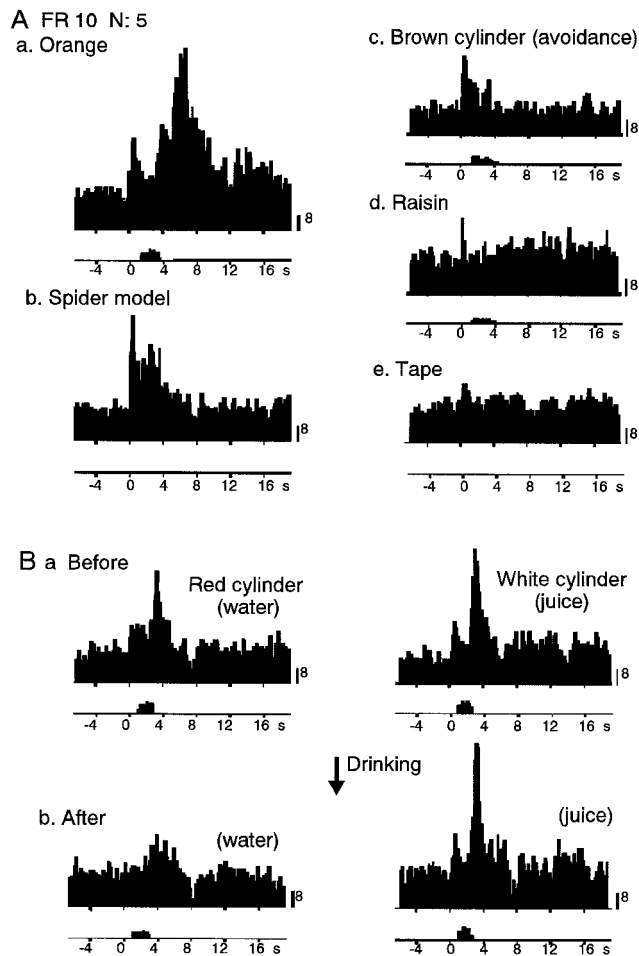

FIGURE 76.2 Modulation of responses of an evaluation-related neuron by satiation in the amygdala. (A) Activity increased in response to preferred food (a), aversion-related objects (c), and new object (b), but not in response to familiar less preferred food (d) or neutral nonfood (e). (B) Modulation of neuronal responses during discrimination and ingestion phases by satiety to water. Responses to sight of water-associated red cylinder and water ingestion decreased after

drinking water (80 ml), but responses to sight of juice-associated white cylinder and juice ingestion did not change. Bar presses: histogram on time scale. Abscissas: time, seconds; zero, W1 open; each histogram bin, 200 ms. Ordinates: summed responses for N trials as indicated. FR: fixation ratio. Histogram pairs upper and lower show firing rates and bar presses totalled for N trials, respectively.

10-30). The last bar-press opened W2 and the animal could then take the object and ingest it if it was desirable food (figure 76.1A,b, solid line). Similarly, when the FR criterion was met in the drinking portion of the task, W1 was automatically closed and a drop of potable liquid (juice or water) portended by some symbolic object (white or red cylinder, cube, etc.) could be licked from a small spout (figure 76.1A,b, dashed line). A white or red cylinder was usually associated, respectively, with juice or water, for example. In the avoidance situation of the task, a brown cylinder, for example, was associated with a weak electric shock. If the animal saw the brown cylinder and heard the 1200-Hz tone, it had to complete an FR schedule within 4-6 seconds to avoid electric shock. The last bar press closed W1 (figure 76.1A,b, dashed line).

RESPONSE CHARACTERISTICS OF THE AM NEURONS
More than 1500 AM neurons were tested by recording activity changes in response to various objects or to stimulation of various sensory modalities that did or did not have affective significance. Since detailed sensory responsiveness of the AM neurons was reported previously (Nishijo et al., 1986; Nishijo, Ono, and Nishino, 1988a, 1988b), here we present the data showing that AM neurons are involved in ongoing evaluation of sensory stimuli.

About one-fourth of the AM neurons differentially responded to various objects with biological significance during visual stimulation (differential vision-responsive neurons). These AM neurons responded strongly to the sight of unfamiliar objects regardless of whether they were food or nonfood. Among these differential vision-responsive neurons, more than half responded consis-

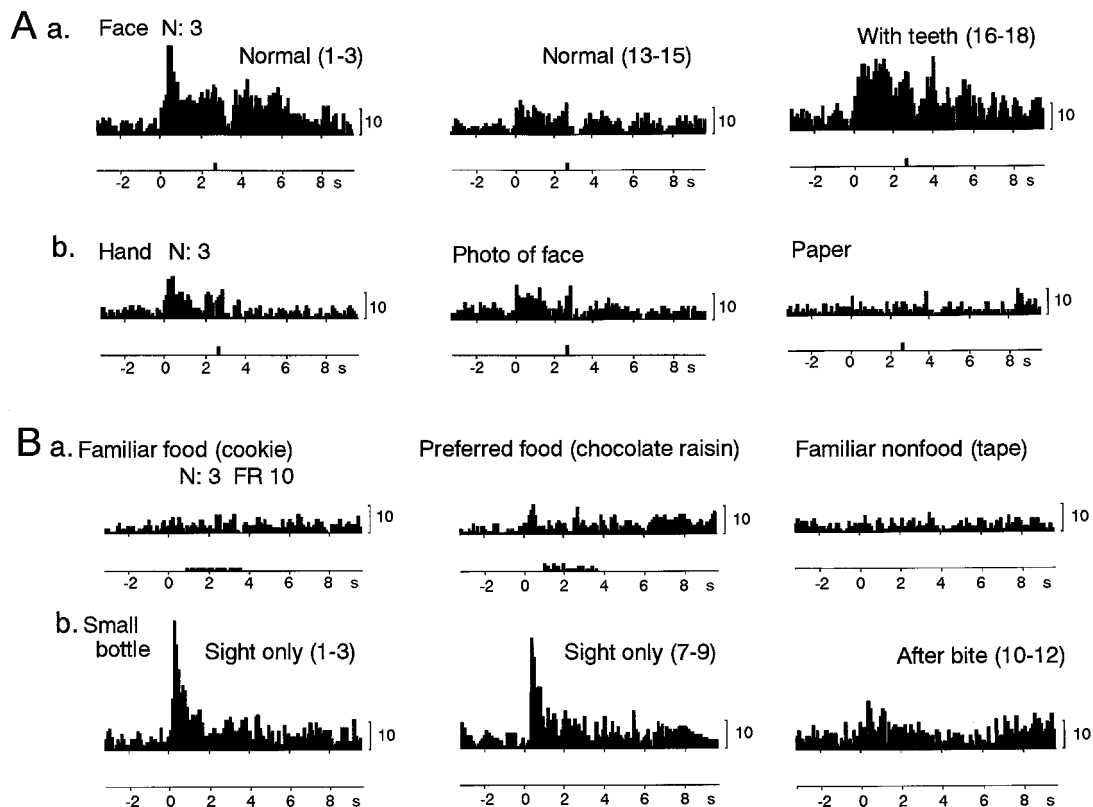

FIGURE 76.3 Responses of specific neurons displaying modulation of responses. (A) A specific neuron responded to certain objects including real human faces. (a) Neuronal responses to a real normal human face (Normal) gradually decreased in repeated trials. However, the activity of the neuron increased when a face with open mouth (With teeth) was presented. (b) The neuron responded to a real human hand and a photo of face, but not to a piece of paper. In a and b, the stimulus was presented by a shutter with an aperture of 15 cm. (B) Responses of a specific neuron that showed response habituation.

tently to rewarding objects such as familiar food and the red or white cylinders associated with water or juice, as well as to aversive nonfood objects such as the brown cylinder that was associated with electric shock, a syringe, a glove, and so on, but not to neutral nonfood objects (tape) (evaluation-related neurons). The remaining differential vision-responsive neurons responded to not all but some of visual stimuli with biological significance (specific neurons).

The response magnitude of evaluation-related neurons was significantly different in response to different objects in that the neuron responded more strongly to more preferred food than to less preferred food. Another characteristic of these neurons was that response magnitudes of the neurons were modulated by satiation. A typical response of one neuron of this type, located in the cortico-medial group of the AM, is shown in figure 76.2. This neuron responded strongly to preferred food (figure 76.2A,a, orange) and weakly to regular food (figure 76.2

(a) The neuron did not respond to familiar regular food (cookie), familiar preferred food (chocolate raisin), or familiar nonfood (tape). (b) The neuron responded to a small bottle from the 1st to the 9th trials. Note that the neuron did not respond to it after the monkey took and bit it in the 10th to 12th trials. Numbers in parentheses indicate order of trials in sequential presentation. Abscissas: time, seconds; zero, shutter opening; each histogram bin, 100 ms. Histogram on time scale in A indicates accumulated trigger signals indicating shutter closing. Other descriptions as for figure 76.2.

A,d, raisin) and less to neutral nonfood (figure 76.2A,e, tape) although all of these were familiar to the animal. It also responded to a punishment-associated object (figure 76.2A,c, brown cylinder) and to an unfamiliar but potentially aversive object (figure 76.2A,b, spider model). Then, this neuron was tested with satiation. Before satiation, the neuron responded to sight of both red and white cylinders, and to ingestion of both water and juice (figure 76.2B,a). After the drinking of 80 ml of water, responses to the water-associated red cylinder and to water ingestion decreased, but responses to the juice-associated white cylinder did not change (figure 76.2B,b).

Most AM neurons including both evaluation-related and specific neurons display habituation of neuronal responses to the stimuli in repeated trials. Results suggest that response habituation to a given object is attributed to changes in biological significance of the object during the trials, rather than to simple sensory habituation. Figure 76.3A shows an example of such an AM

A. Evaluation-related

B. Specific

FIGURE 76.4 Recording sites of the evaluation-related (A) and specific neurons (B) in the amygdala. Numbers below each section indicate distance (mm) anterior from interaural line.

neuron that responded to specific stimuli such as human faces. Although the neuron did not respond to familiar foods and nonfoods (data not shown), it responded strongly to a real human face with a closed mouth (figure 76.3A,a). It also responded to a human hand and a photo of a human face, but not to a plain piece of paper (figure 76.3A,b). When the neuron was tested repeatedly with the same human face, responses to the face gradually decreased from 1st to 15th trials. However, neuronal responses to the face increased again when the human face with open mouth was presented to the monkey (figure 76.3A,a). Figure 76.3B illustrates another example of a specific AM neuron that showed response habituation in repeated trials. The neuron responded specifically to a small bottle (figure 76.3B,b). The neuron continued to respond to the small bottle from the 1st to 9th trials (figure 76.3B,b). However, the responses to the small bottle suddenly decreased after the monkey took and bit it. These results suggest that a decrease in neuronal responses reflected a decrease in the biological significance of objects. This habituation of neuronal responses to objects including faces is consistent with a recent PET study in which an

increase in cerebral blood flow in the AM in response to fearful and happy faces rapidly habituated in repeated trials (Breiter et al., 1996). The recording sites of evaluation-related and specific neurons are depicted in figure 76.4. Although both types of AM neurons were located in the lateral, basolateral, basomedial, and corticomedial group of the AM, specific neurons were located mainly in the basal nuclei (i.e., lateral, basolateral, and basomedial nuclei of the AM).

Some AM neurons were further tested with either complex objects such as a walking human or specific situations (or contexts) in which food delivery was expected. Figure 76.5 illustrates an example of an evaluation-related neuron that was tested with human movements. The neuron was initially tested with several foods and nonfoods. The neuron responded to the sight of familiar food such as a cookie (figure 76.5A,a) and a piece of raisin (not shown). When the neuron was tested with a piece of raisin that was slightly salted on its hidden side, the monkey ate it in 3 successive trials. The neuron responded strongly to the sight and ingestion of the salted raisin during these trials (figure 76.5A,b). However, the neuronal responses to the

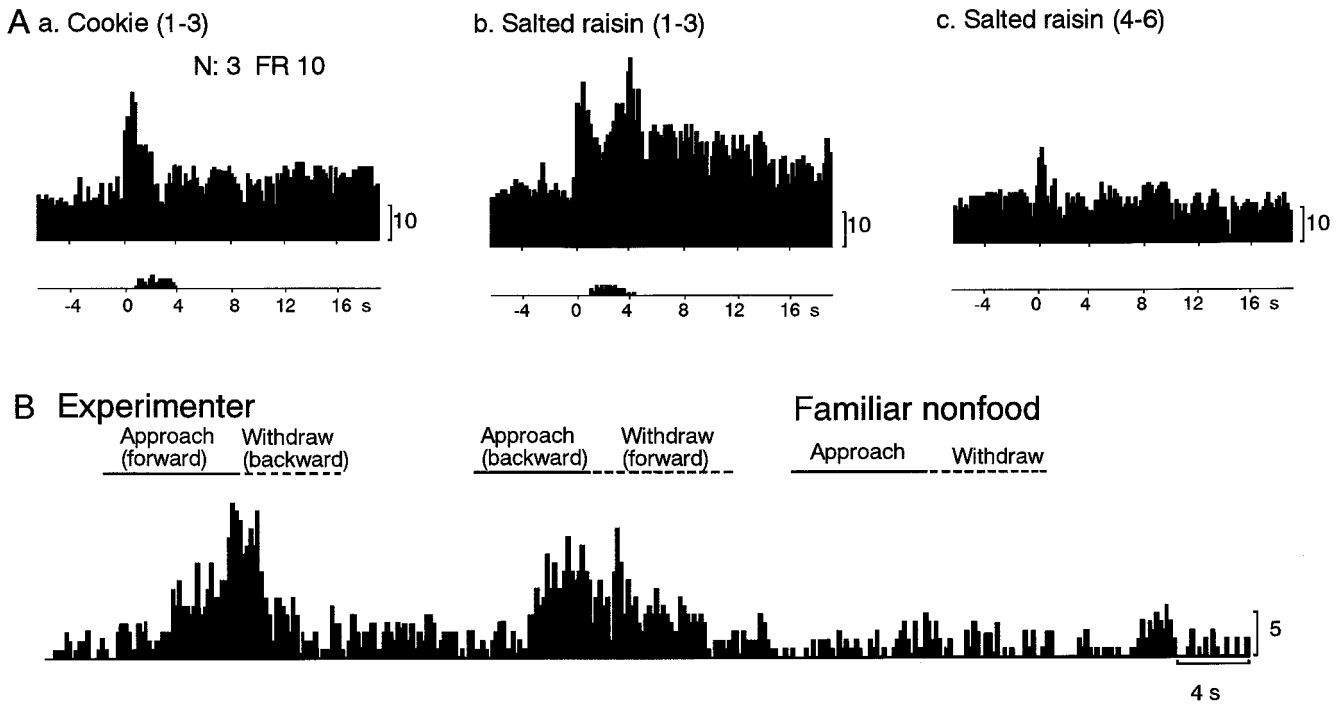

FIGURE 76.5 Responses of an evaluation-related neuron that responded to various objects and human movements. (A) The neuron responded not only to familiar regular food (a, cookie), but also to sight and ingestion of a salted raisin (b). After the monkey ate it, responses to the sight of a salted raisin decreased (c). (B) Activity of the neuron increased in response to human movements. The activity of the neuron gradually increased when the experimenter approached by walking forward, toward the monkey, and decreased when the experimenter withdrew

from the monkey by walking backward. When the experimenter approached by walking backward and withdrew by walking forward (i.e., walking toward and away from the monkey with the back toward the monkey), the activity of the neuron similarly changed. However, the activity of the neuron did not change when the familiar nonfood (tape) was moved toward and away from the monkey. Solid line, approaching; dashed line, withdrawing. Each histogram bin, 200 ms.

salted raisin suddenly decreased in the subsequent three trials, and the monkey did not eat it (figure 76.5A,c). Since the neuron also responded strongly to the sight and ingestion of familiar preferred foods such as a piece of orange (data not shown), these results suggest that the neuronal responses were related to evaluation of biological significance of the objects. The neuron was then tested with human movements (figure 76.5B). When the experimenter approached, by walking forward, toward the monkey, the activity of the neuron gradually increased. When the experimenter withdrew from the monkey by walking backward, the activity gradually decreased. Furthermore, when the experimenter approached by walking backward and withdrew by walking forward (i.e., walking toward and away from the monkey with the back toward the monkey), the activity of the neuron similarly changed. However, the activity of the neuron did not change when the familiar nonfood item (tape) was moved toward and away from the monkey. All of these data were consistent with the idea that this neuron was related to evaluation of biological significance of the stimuli in a context-dependent manner.

Figure 76.6 shows an example of a specific neuron displaying activity changes in relation to reward expectancy. The neuron responded to familiar food (A,a, cookie), but less to familiar nonfood (A,b, tape). Furthermore, the neuron responded to hand extension toward the stage behind the shutter by the experimenter (A,c, hand extension). Usually, food and nonfood trials followed hand extension. However, the responses to hand extension gradually decreased if the experimenter extended his hand repeatedly without food trials (data not shown). Figure 76.6B shows raw records of the same neuron during the trials. The activity of the neuron increased in response to the sight of food (cookie) after W1 and W2 opening (open triangles and last filled triangles, respectively, in B,a–c). When fixation ratio (FR) was suddenly increased to 20 in Bb, the activity increased not only after W1 and W2 opening, but also at the moment corresponding to W2 opening in the regular trials with FR 10 schedule in Ba. However, the activity did not increase at the same moment of the third trial with FR 20 schedule in Bc. These results suggest involvement of the AM neurons in evaluation of biological significance of objects in specific contexts.

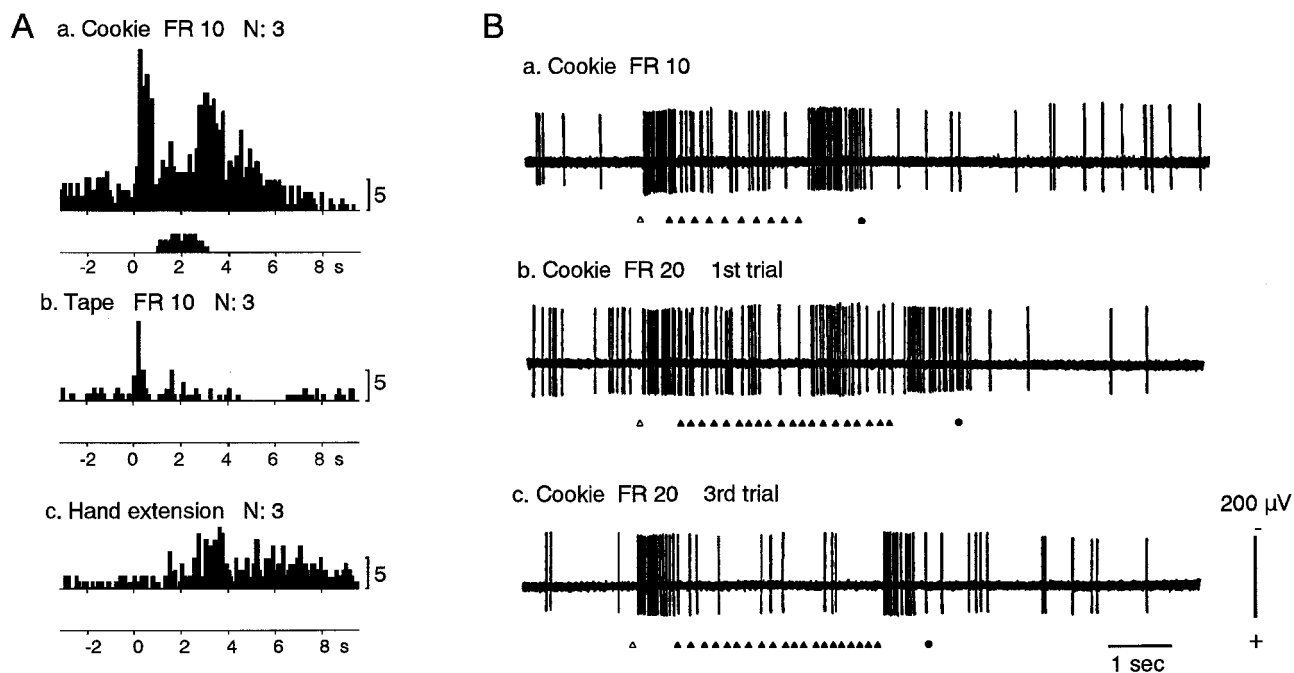

FIGURE 76.6 Responses of a specific neuron, activity of which increased in a specific context. (A) The neuron responded to a familiar regular food (a), but not to a tape (b). Activity of the neuron increased in response to hand extension by an experimenter (c). Each histogram bin, 100 ms. Other descriptions as for figure 76.2. (B) Responses of the neuron in food trials shown as raw records. Activity increased in response to sight of

a cookie after W1 and W2 opening (open triangles and last filled triangles) in the trials with FR 10 and 20 schedules (a–c). Note that, in the 1st trial with FR 20 (b), the activity also increased during bar pressing at the moment corresponding to W2 opening in the regular trials with FR 10 schedule. Open triangles, times W1 opened; filled triangles, bar presses; filled circle, food put into mouth.

EFFECTS OF REVERSAL ON AM NEURONAL ACTIVITY
Some AM neurons were tested with alteration of affective significance of the food objects by salting foods. Not only visual but also ingestion responses of the neurons were attenuated by salting. Figure 76.7 shows such modulation of responses of the neuron that responded to both sight and ingestion of some foods. The neuron may have responded slightly in the late ingestion phase to a white cylinder associated with juice and to a cookie in trials 1 and 2. In the visual and ingestion phases, this neuron responded to apple, potato, raisin, and orange in trials 3–5, 9, and 13–15. The response differences to the various food stimuli showed no correlation with mouth movement and neuronal activity. In addition, in our feeding paradigm, mouth movement was slight or absent during the discrimination and bar-press phases. This fact suggests that the neuronal responses preceding ingestion were not preparatory to mouth movement. Similarly, bar-pressing behavior did not correlate with neural activity in trials 6, 13, and 14, but visual presentation of a normally ingested food did elicit activity in trials 9 and 15. The neuron represented in figure 76.7 did not respond to any known aversive or neutral objects such as the brown cylinder that was associated with electric shock, a syringe, tape, or salted orange (trials 6–8,

12, and others, not shown). Trials 9–15 show the effects of salting food. The attenuation was apparent during both the visual inspection and ingestion phases of the task. In the first salted food trial (trial 10), the response disappeared immediately after the animal put salted orange into its mouth. Salting of food was always done in such a way that the salt could not be seen, so it was first detected by the animal upon ingestion. The response to the sight of orange diminished in subsequent salted food trials (trials 11 and 12), as well as in the first two unsalted food trials that followed (trials 13 and 14). After the experimenter gave a piece of unsalted orange to the animal by hand, bar pressing to obtain orange began again in trials 13 to 15, and neuronal responses to the sight and ingestion of orange quickly recovered.

It should be noted that neuronal responses were first suppressed during the initial ingestion of salted food; suppression of visual responses then followed although the visual appearance of the food was the same. In preliminary experiments, we also observed suppression of gustatory responses by quinine that was similar to the suppression by salt that is reported here. The gustation phase of ingestion is an important factor in the evaluation of food palatability (Bartoshuk, 1989). All this evidence suggests that the suppression of neuronal activity

FIGURE 76.7 Modulation of responses of a specific neuron by reversal tests. Neuronal responses are shown by raster display. The neuron responded slightly to the ingestion of juice and cookie in trials 1 and 2. Activity increased primarily in and immediately preceding ingestion phase in trials 3–5. Note no neural response in bar press phase in avoidance trial (trial 6).

Trials 9–15 show reversal associated with salted food. Note that neural response disappeared at the moment when the animal put salted orange into its mouth (arrow in trial 10). Abscissas: time, seconds; W1 opened at time 0. Each filled triangle below a raster display indicates one bar press.

discussed here is related to aversion to salted food. This speculation is reasonable, since behavioral responses were also suppressed after the first of a series of salted food trials. Thus the conclusion based on ingestion that salted food was aversive led to a judgment that visual appearance of the same food was aversive (suppression of visually dependent neural responses). This dependence of visual responses on ingestion sensation suggests that these neurons were involved in stimulus (visual stimulus)–affect (ingestion sensation, possibly gustatory) association (i.e., visual-oral sensory association) (Geschwind, 1965; Nishijo, Ono, and Nishino, 1988a,b).

RELATIONS TO BAR-PRESS BEHAVIORS The analysis of the relation between neuronal and behavioral responses indicates one important characteristic of AM neurons. There was not always a direct correlation between rate or amount of bar pressing and neuronal activity, and no direct correlation between individual bar presses and neuronal activity in the AM (direct, one-to-one motor-coupled response) was ever observed. Although spontaneous bar pressing during intertrial intervals was rare, when such spontaneous pressing did

occur, no concomitant neuronal activity change was ever observed. In high-FR (FR 20) trials the responses of the AM neurons returned to the control level during bar pressing and then reappeared when the shutter was opened after the last bar press (figure 76.6B,c, third trial). Even when there was no bar pressing, AM neurons would respond to the sight of biologically significant objects. In the bar-press phase, the animal usually looked at the window, and AM neuron responses in that phase depended on the affective nature of the objects. During the bar-press phase, responses of some neurons to the most preferred food were significantly stronger than responses of the same neurons to less preferred food. Nevertheless, differences in the duration of the bar-press phase, which was inversely related to the rapidity of bar pressing, were not statistically significant, except in reversal tests when some confusion might be expected. However, there was some apparent tendency toward indirect relations between neuronal and behavioral responses. For instance, stronger neuronal responses accompanied normal bar pressing, but the same neurons responded less vigorously when bar pressing was delayed or absent (figure 76.7)

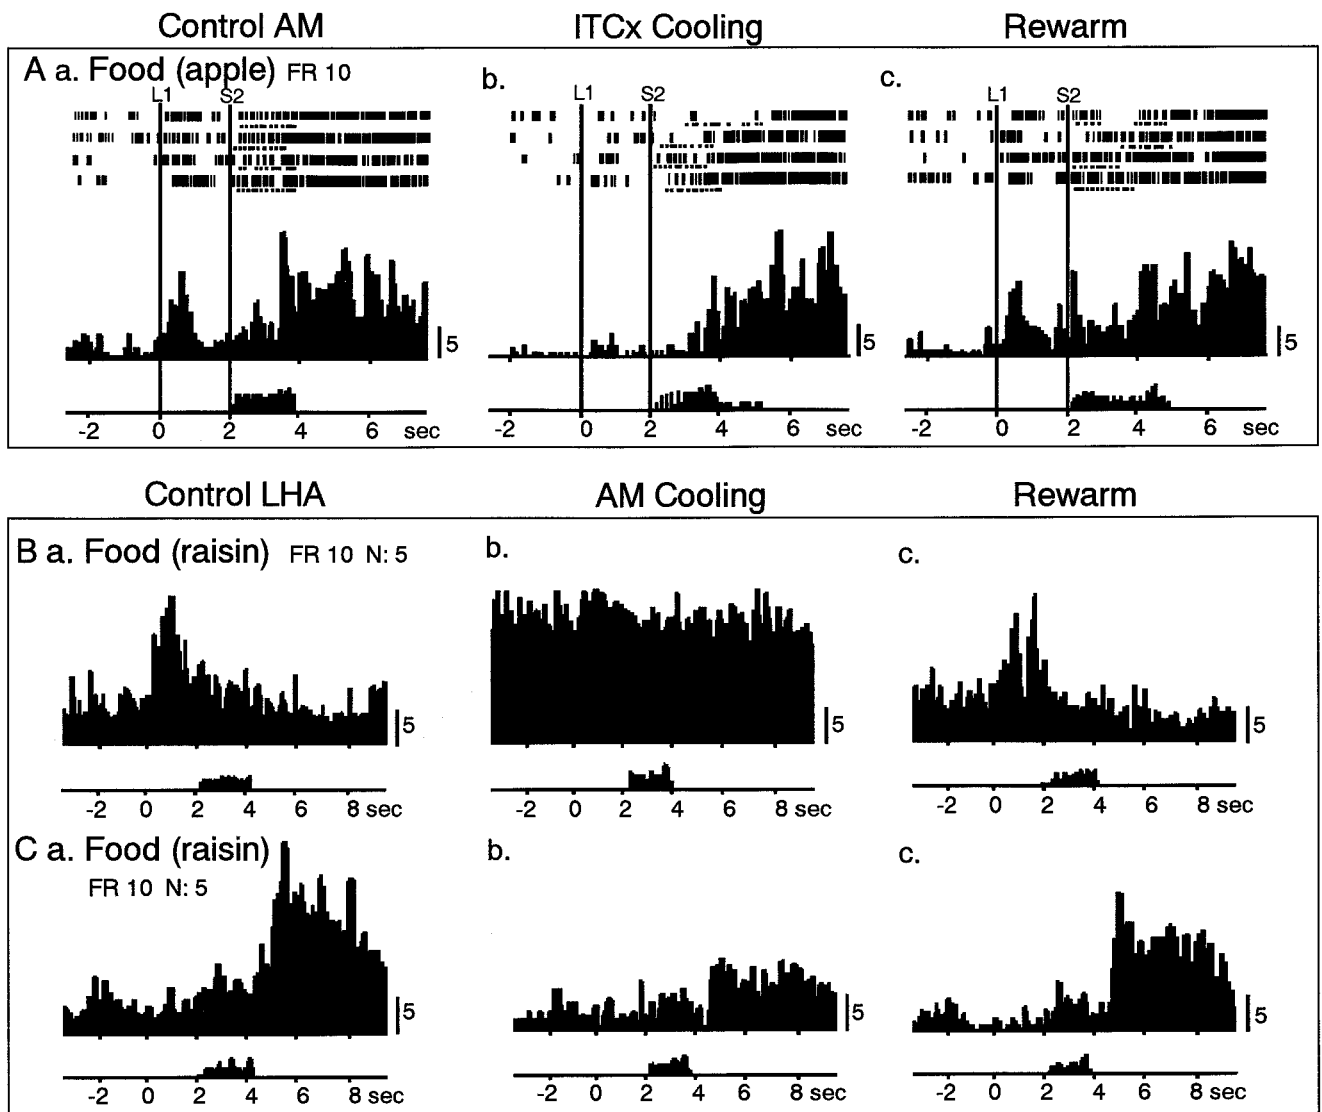

FIGURE 76.8 Effects of cooling of the inferotemporal cortex (ITCx) and amygdala (AM) during a visual discrimination task. (A) Effects of ITcx cooling on AM food-predominant neurons. Raster displays and histograms (80-ms bins, 10.24 s) show neuronal responses to the sight of food (apple) before ITcx cooling (a), during cooling (b), and after rewarming (c), and bar presses (lower histogram of each set) for 4 trials. Time L1 (0), light on; S2, shutter in front of bar opened. Note no visual responses to the sight of food during ITcx cooling (b). (B) Effects of AM cooling on LHA food-predominant neurons. Histo-

grams (100-ms bins, 12.8 s) represent responses for 5 trials during control (a), AM cooled (b), and rewarmed (c) states. No significant visual responses to sight of food during AM cooling, although spontaneous firing rate increased remarkably (b). (C) Effects of AM cooling on responses of ingestion-related LHA neurons. Neuron responded substantially before (a) and after (c), but less during AM cooling (b). Histograms: accumulated in 5 trials (100-ms bins, 12.8 s). Other descriptions as in figure 76.8A.

as in reversal trials. Our present results imply that neuronal activity in the AM is not directly related to sensory inputs nor to overt acts of the animals. Neuronal activity may, however, reflect evaluation of the biological significance of an object. Consequently, it may reflect motivational aspects of an animal's behavioral responses and an animal's attention to a biologically significant object among various exteroceptive stimuli.

Disconnection experiment by reversible cooling of ITcx or AM

To test disconnection of visual inputs to the AM, cooling probes were chronically implanted bilaterally over the dura of the anterior inferotemporal cortex (ITCx) in one monkey; and to disconnect between the AM and the hypothalamus, cooling probes were chronically implanted in the bilateral AM in two monkeys. In this ex-

periment, the modified version of the task was used (figure 76.1B). The monkey could see an object on a stage through a one-way mirror (S1) in front of the stage when a light was turned on. However, another shutter (S2) prevented access to the bar. After a delay of at least 2 seconds, S2 was opened automatically. The S1 shutter was opened by the last bar press. The monkey's behavior and the neuronal responses were essentially the same in this and the previously described situation.

The ITCx cooling suppressed discriminative responses of some AM neurons to various objects. Figure 76.8A shows one example of such modulation by ITCx cooling. Before cooling, the neuron activity increased at the sight of food and during ingestion in all trials (A,a). About 3 minutes after the start of ITCx cooling, the visual responses to the sight of food disappeared in each of the four trials (A,b). Inferotemporal cortex cooling did not change responses of this particular neuron during ingestion (A,b). Thus the main AM responses to ITCx deficits were depression of vision-related neuronal responses and spontaneous firing rates. Previous recording studies indicated that some ITCx neurons responded to only one pattern regardless of size or color (Gross, Bender, and Rocha-Miranda, 1969; Sato, Kawamura, and Iwai, 1980; Desimone et al., 1984) or to specific colors (Fuster and Jervey, 1982; Desimone et al., 1984). The results reported here along with the previous studies strongly suggest that the ITCx is in one of the paths of object-related information passing from the visual cortex to the AM.

Effects of AM cooling on the LHA neuron responses are shown in figure 76.8B,C. The LHA neuron responded preferentially to the sight of food (B,a). During AM cooling, no excitatory visual response was significantly greater than the background activity, since the spontaneous firing rate was greatly increased by bilateral AM cooling (B,b). In contrast to the effects of ITCx cooling on AM responses in the ingestion phase, AM cooling depressed the responses of LHA neurons that responded in the ingestion phase (figure 76.8C). In summary, AM cooling mainly depressed excitatory or inhibitory LHA responses related to visual and ingestion signals, and decreased or increased the spontaneous firing rates of LHA neurons. This finding is consistent with our previous studies in which the effects of AM stimulation on LHA neurons were generally caused by either inhibition or disinhibition (Oomura, Ono, and Ooyama, 1970; Ono, Oomura, et al., 1981; Oomura and Ono, 1982). Taken together, our analysis of neural relations between the ITCx, AM, and LHA in the monkey indicates that the AM mediates integration and links between the ITCx and LHA. Rolls (1981) suggested a

similar notion, since latency to visual stimuli increased from the ITCx to the LHA.

Neuronal responses of monkey anterior cingulate neurons to biologically significant objects

In this experiment, a modified version of the task was used (figure 76.1B) (Nishijo et al., 1997). Anterior cingulate neurons also responded to biologically significant objects. Figure 76.9A shows an example of an AC neuron that responded to certain foods. This neuron responded to rewarding objects, cookie (a) and apple (b), but not to the brown cylinder associated with avoidance (aversive electric shock) (c) or a yellow cylinder that had no association (d). Responses of this vision-related differentiating neuron to various food and non-food objects are compared in figure 76.9B. Each histogram shows the mean firing rate for 2 seconds in 4 trials after the light was turned on minus spontaneous firing rate. This neuron responded to rewarding objects, such as familiar food (apple, raisin, cookie, and white cylinder associated with juice), but did not respond to familiar aversive objects (syringe, frog model, and brown cylinder associated with aversive electric shock), a neutral yellow cylinder, or an unfamiliar object (blue tape). In the reversal tests in which the meanings of objects were changed, responses of these neurons to rewarding or aversive objects were readily suppressed. Another type of AC neurons responded to both familiar rewarding objects, such as apple, raisin, cookie, and white cylinder associated with juice, and familiar aversive nonfood objects, such as syringe and familiar cylinder associated with electric shock, but not to a neutral object. These neurons also responded strongly to unfamiliar objects. The response magnitudes of these neurons to rewarding objects were correlated to the animal's preference (not shown). These results indicate AC neurons could encode emotional or motivational information. Suppression of neuronal responses in the reversal tests strongly suggests that the responses were related to the rewarding or aversive nature of a stimulus. Neurophysiological results in the former section as well as those in the previous lesion studies (Jones and Mishkin, 1972) suggest that the AM is involved in evaluation of biological significance of a stimulus, which is important in discrimination of food (rewarding) from nonfood (nonrewarding). Anatomical study indicates that the AC receives strong projections from the AM (Vogt and Pandya, 1987). Our present study suggests that responsiveness of a class of the AC neurons is very similar to that of AM neurons and that the AC is also involved in evaluation of the biological significance of a stimulus.

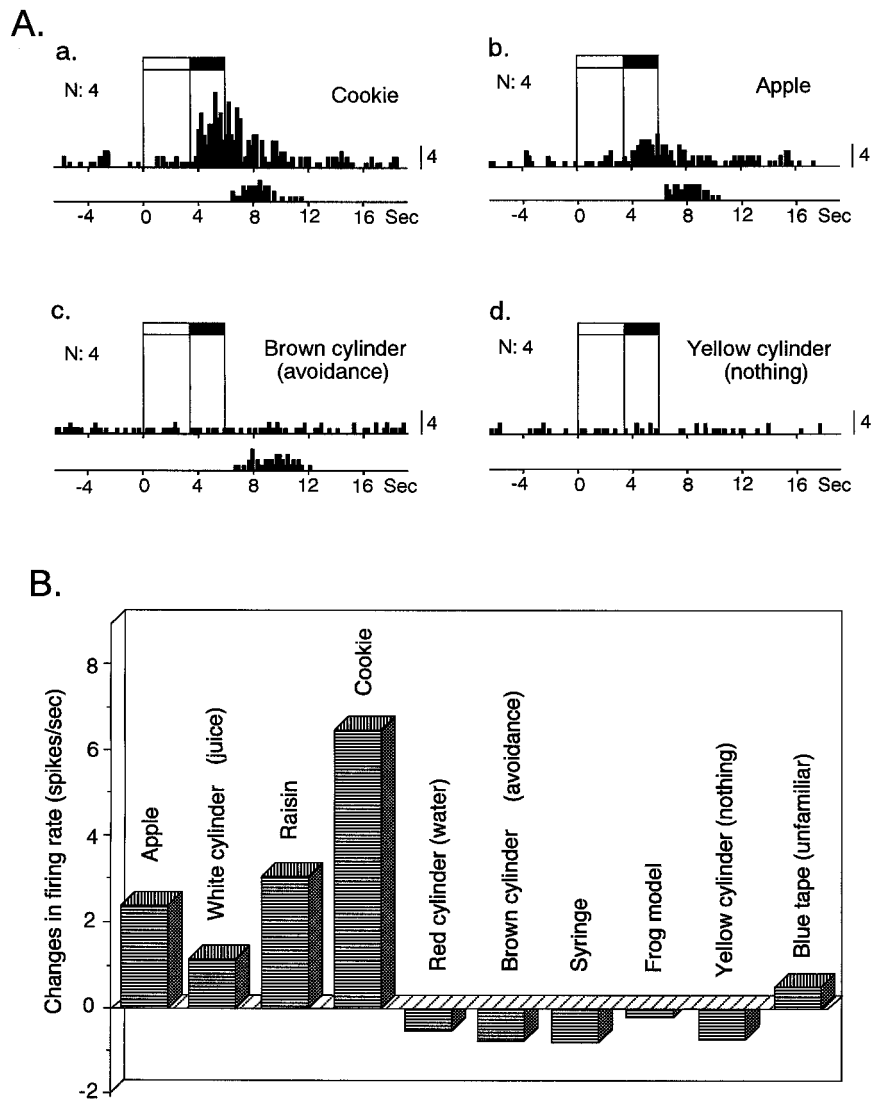

FIGURE 76.9 Responses of a differential vision-related neuron in the anterior cingulate cortex. (A) Responses to various objects with and without biological significance. The neuron responded to rewarding objects: cookie (a) and apple (b), but not to a brown cylinder associated with electric shock (c) or a yellow cylinder with no association (d) during visual discrimination phase. Upper histogram (200-ms bin), summed neuronal responses of 4 trials with the object indicated; lower histogram, bar presses. Zero on time scale, onset of start tone. Open strip,

delay phase between the start tone and visual stimulation; black strip, visual discrimination phase. Calibration at right of each histogram: number of spikes per bin. (B) Summary of responses of the neuron shown in figure 76.9A to various food and nonfood objects. Each column shows response magnitude after the indicated object was presented, measured as mean discharge rate (spikes/second) for four 2-second intervals minus spontaneous rate.

However, there were substantial differences between the AM and AC. It should be emphasized that some AC neurons responded mainly in the bar-press phase (bar-press-related neurons). Such neurons were not observed in the AM. Figure 76.10 illustrates an example of a typical bar-press-related neuron. This neuron responded during bar pressing to obtain food (A, cookie; B, juice), but not during bar pressing to avoid shock (C) (differential bar-press-related neurons). These responses of the differential bar-press-related neurons cannot be attributed to simple motor response. However, neuronal re-

sponses of these neurons were correlated to the bar-press phase when delays were imposed before or after the bar-press phase (not shown). The results indicated that these neuronal responses were related to both bar presses and affective significance of the objects. This finding suggests that these neurons were related to positive or negative motivation for motor performance. Another type of bar-press-related neurons responded not only during bar pressing to obtain food, but also during bar pressing to avoid shock (nondifferential bar-press-related neurons). Shima and colleagues (1991) observed

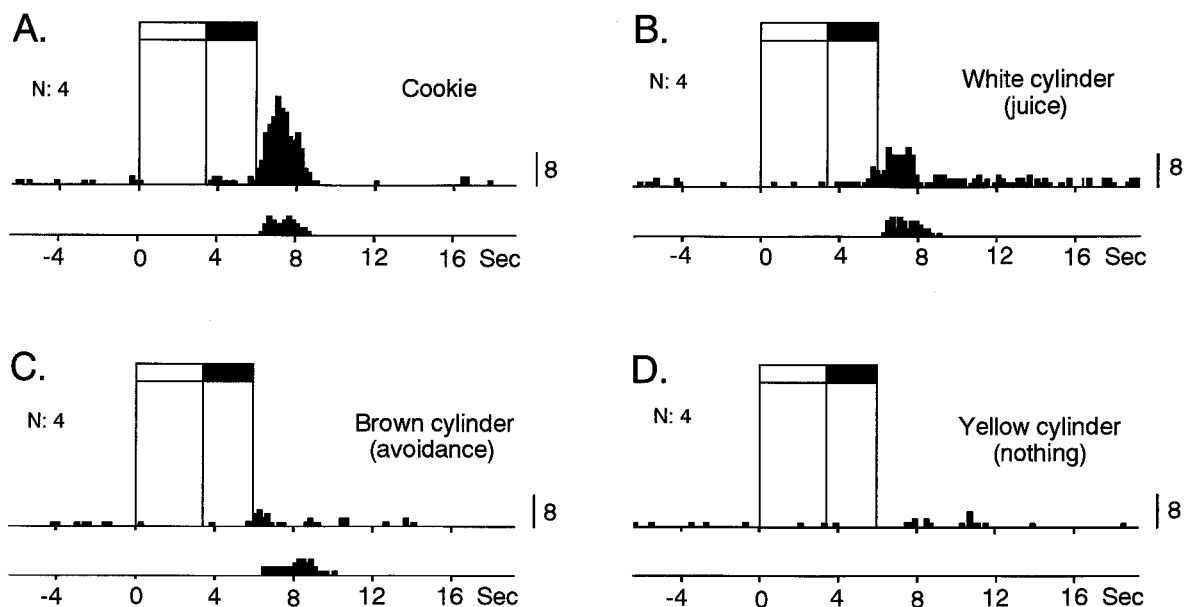

FIGURE 76.10 Responses of a differential bar-press-related neuron in the anterior cingulate cortex. The neuron responded mainly during the bar-press phase only for cookie (A) and

juice (B), but not for avoidance (C) or a neutral object (D). Other descriptions as for figure 76.9.

two foci of movement-related neurons in the posterior part of the AC, with the anterior part being more significant in the self-paced than in the sensorily triggered movements. The loci of nondifferential bar-press-related neurons in the present study were comparable to the anterior sites of the movement-related neurons described by Shima and colleagues (1991). Anatomical studies suggest that these movement-related areas of the AC project to motor and premotor cortices and basal ganglia (Royce, 1982; Yeterian and Van Hoesen, 1978). The results in the present study, together with anatomical results, suggest that the cingulate cortex is important in motivation for motor performance.

Various types of AC neurons were located topographically. Differential vision-related neurons were located more anteriorly than bar-press-related neurons. Differential and nondifferential bar-press-related neurons were located in the mid and posterior portions of the AC, respectively. The anterior part of area 24 receives inputs from the prefrontal cortex and other emotion-related areas such as the AM (Vogt and Pandya, 1987), and projects to its posterior part, which in turn projects to motor and premotor cortices and basal ganglia (Royce, 1982; Yeterian and Van Hoesen, 1978). This anatomical and neurophysiological evidence suggests that sensory information is processed and transformed to motor command from the anterior to the posterior portions of the AC. Results of lesion and stimulation studies were consistent with this idea. Lesion of the AC results in deficits in the control of complex motor behavior

such as emotional and active avoidance behaviors (Gabriel, 1990; Gabriel et al., 1991; Vogt, David, and Olson, 1992). Electrical stimulation of the AC in man elicits various types of highly integrated motor behavior (Thalairach et al., 1973). Our results suggest that the AC integrates inputs from other emotion-related areas and frontal cortex, and sends the information to motor executive centers to behave appropriately in a variety of specific motivational or emotional contexts.

Functional consideration of the amygdala and anterior cingulate cortex in humans

The present results strongly suggest that the AM is involved in evaluation of the biological significance of incoming sensory information. This conclusion is consistent with recent neuropsychological studies in humans. The patient with AM bilateral damage could evaluate neither facial expressions (Adolphs et al., 1994, 1995) nor emotional intonation of speech (Scott et al., 1997). Recent PET and fMRI studies have demonstrated that cerebral blood flow in the AM of normal humans increased when subjects looked at photos of faces with emotional expressions (Morris et al., 1996; Breiter et al., 1996), unpleasant pictures (Irwin et al., 1996), and human movements (Bonda et al., 1996). These results along with our neurophysiological results suggest that the AM is one of the receptive areas of emotion in the brain, although Papez supposed that the cingulate gyrus had such functions (Papez, 1937).

However, cerebral blood flow consistently increased not only in the AM but also in the AC of normal subjects who voluntarily recalled emotional events (George et al., 1995). Similarly, cerebral blood flow in those areas increased in normal subjects who experienced hallucination by intravenous injection of procaine (Ketter et al., 1996) and in normal subjects who dreamed during REM sleep (Maquet et al., 1996; Braun et al., 1998). These results suggest that activation of the AC might evoke emotional experience without external sensory inputs. Furthermore, cerebral blood flow in the AC as well as the AM increased in patients with emotional disturbances such as posttraumatic stress disorder, simple phobia, and obsessive-compulsive disorder who could not control their emotionally negative thinking (Rauch et al., 1994, 1995, 1996). This finding suggests that abnormally elevated activity of the AC might result in excessive thinking of negative ideas in these patients.

Taken together, all this evidence suggests some functional differences between the AM and AC; the AM is primarily involved in evaluation of incoming external sensory inputs, while the AC might be involved in internal or voluntary generation of emotion without external sensory inputs. We reported the existence of differential bar-press-related AC neurons involved in positive and negative motivation. These AC neurons might be involved in internal or voluntary generation of emotion. In the preceding section we suggested that inputs from the other emotion-related areas and the prefrontal cortex are transformed to motor behaviors in the AC by sending its outputs to motor executive centers. Similarly, the AC might integrate that information to generate appropriate emotion by sending its outputs to the AM. Taken together, the AM and AC are crucial in emotional and motivated behaviors of primates including humans. Understanding the functions of these areas will contribute to elucidation of various human emotional disorders associated with inappropriate behaviors.

ACKNOWLEDGMENTS We thank Dr. Patrick D. Martin, Toyama Medical and Pharmaceutical University, for advice and help with the manuscript. Emotional Processing in the Human Brain Revealed through Functional Neuroimaging

RAYMOND J. DOLAN

ABSTRACT The mechanisms by which sensory events that represent fear are processed in the human brain provides a general model for understanding emotional function. This chapter presents functional neuroimaging data from studies of fear processing and relates these to a neurobiological model of emotional processing. A critical role for the amygdala in processing sensory stimuli that signal fear is highlighted. The time course of an amygdala response to behaviorally relevant sensory inputs shows rapid habituation. When a previously neutral stimulus acquires an ability to elicit fear, this acquisition is expressed in plasticity changes in related sensory processing regions. This adaptive learning also involves context-specific changes in connectivity between sensory processing regions and regions such as the amygdala that mediate value. Using masking procedures, which disrupt conscious awareness of a target stimulus occurrence, privileged access to the amygdala for sensory stimuli that signal fear can be demonstrated.

This chapter provides a neurobiological perspective on emotional processing in the human brain informed principally by functional neuroimaging. The focus is on an exemplar emotion, fear. I begin with a psychological analysis of fear and its relation to other so-called basic emotions. I then present a neurobiological model of emotional processing, framed in terms of value-dependent learning. This model is subsequently used to formulate questions and interpret findings from empirical neuroimaging experiments. The type of questions addressed include the following: How does the brain process behaviorally relevant sensory stimuli? To what degree is processing of fear-inducing stimuli dependent on conscious awareness? What dynamic neural events ensue when a salient sensory stimulus activates a fear-processing system? What neural mechanisms enable a neutral sensory stimulus to acquire behavioral significance? What is the time course of activation in critical brain regions that process fear-inducing stimuli?

Concepts and frameworks

Fear is a psychological trait that represents an adaptation to danger. More broadly, it is an evolved pancultural trait homologous to that seen in a wide range of species. Restricting a discussion of human emotion to a single instance, fear, might be considered limiting. However, this approach benefits from the fact that knowledge of fear processing in other species provides constraints for interpretation of human neurobiological data. The more ambitious program of elaborating a general neurobiological account of emotion is conceptually problematic. It is generally accepted that the concept of emotion subsumes a wide range of distinct linguistic categories largely derived from everyday discourse. There are no *a priori* grounds for assuming that these vernacular concepts necessarily reflect the operation of neurobiological systems. Conceptual imprecision, arising from overreliance on vernacular concepts of emotion, has recently resulted in trenchant calls for abandonment or radical reformulation of the entire emotion concept (Brothers, 1997; Griffiths, 1997).

The perspective adopted in this chapter is influenced by a psychoevolutionary approach that reflects a rediscovery of Darwin's views on emotion (Darwin, 1965; Griffiths, 1997). Crucial in this regard is the affect programs concept (Ekman, 1971, 1982; Ekman and Friesen, 1971). This proposes several distinct emotions, termed primary emotions, that include fear, anger, happiness, sadness, disgust, and surprise. These emotions, reflex like in their operation, are expressed in multicomponent behavior patterns including facial, motor, vocal, endocrine, and autonomic responses. It is beyond the present brief to review the relevant supportive evidence. However, critical observations include the recognition of distinct patterns of facial emotional expression, corresponding to primary emotion category labels, across cultures (Izard, 1998; Ekman and Friesen, 1971). The affect program concept does not exhaust the vernacular

concept of emotion. Emotions such as envy, shame, and guilt, among others, do not readily fall within a primary emotion category. One proposal is that they represent a separate category of higher cognitive or secondary emotions (Griffiths, 1997; Damasio, 1995). Distinguishing features of this category are a greater involvement of higher cognition and the fact that they arise almost exclusively within the context of interpersonal relationships.

A model of emotional processing

A simplified model of emotional processing proposes input and output components. An emotional input refers to a sensory stimulus that elicits an emotional state. The high degree of variance in stimuli that elicit primary emotions indicates that most are learned. There is, nevertheless, substantial evidence for innate bias in emotional learning mechanisms. For example, there is facilitation of learning in relation to certain salient stimuli, such as conditioning to angry faces, a form of response preparedness (Öhman, Fredrikson, and Hugdahl, 1976; Seligman, 1971). This learning bias suggests the presence of systems with innate response dis-

positions to particular sensory inputs. By contrast, an emotional output is the behavioral sequel to engagement of an emotional processing system. Primary emotions, including fear, are relatively invariant in their expression, indicating encapsulation of the associated output systems. Whether interactions with other aspects of cognition, such as attention and memory, occur at input or output stages of processing is an unanswered question.

Many neurobiological models of emotion and emotional learning have been articulated based on animal data (LeDoux, 1996). The model that we apply is based upon that of value-dependent learning (Friston et al., 1994) outlined schematically in figure 77.1. The model assumes the existence of epigenetically specified neural systems that respond to signals that have innate adaptive value. Examples of innate value are responses to hunger and sex but might also include prepotent stimuli such as fearful faces. Although not explicitly specified, candidate components of value systems could include the amygdala and basal forebrain regions. Outputs from value systems are proposed to reflect responses to innately salient stimuli but also provide constraints, through selective consolidation of synaptic change, for acquisition of novel adaptive behaviors. Thus a key proposal of the model is

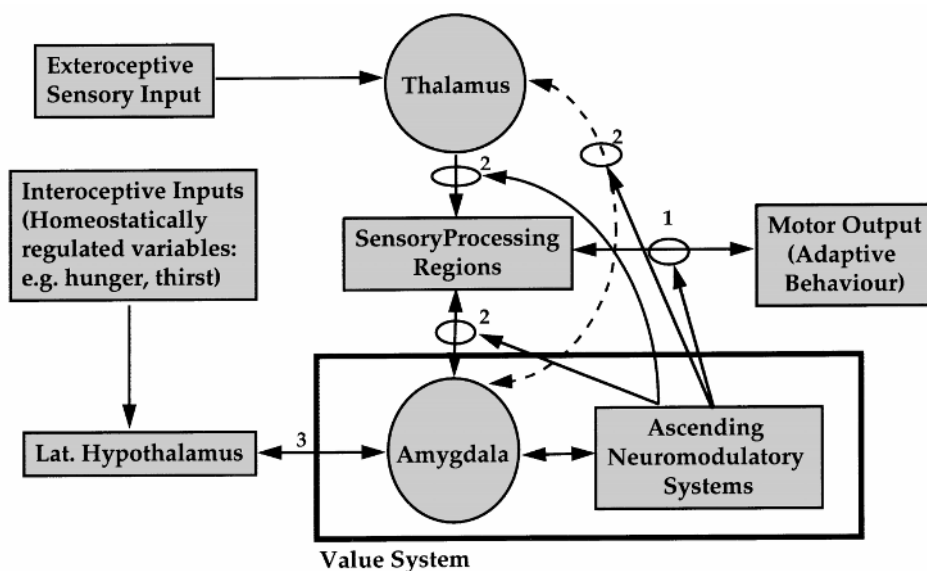

FIGURE 77.1 A schematic model of value-dependent neural selection adapted from Friston and colleagues (1994). The value system, outlined in the large rectangle, represents a mechanism that signals the consequence of behaviors vital for homeostasis. The value system can be engaged by feedback from interoceptive inputs or via sensory inputs to structures such as the amygdala. Activation of the value system sends neuromodulatory signals, which consolidate synaptic changes, to sensory and motor regions, as indicated by arrows and red circles. As a consequence, neural activity (and related behaviors) coincident with events possessing innate value elicit

responses in the value system that mediate emotional or value-dependent learning. The mechanistic basis of this learning has three components designated 1, 2, and 3 in the figure. These correspond to (1) consolidation of adaptive responses (i.e., sensorimotor integration) that mediate procedural learning; (2) mediation of acquired value (i.e., salient cues become reinforcers by virtue of gaining access to the amygdala or value system); and (3) mediation of innate value (i.e., connections to the amygdala specified epigenetically and determined by evolution as opposed to experience-dependent mechanisms).

that stimuli acquire value or behavioral relevance through selective consolidation of afferents to value systems from sensory processing systems. This consolidation itself occurs under the influence of outputs from value systems. Emotional learning is therefore considered a “bootstrap” procedure where autodidactic acquisition of adaptive responses, to stimuli with acquired value, can be traced back to reinforcers with innate value selected on an evolutionary time scale. For example, in a classical conditioning experiment, an aversive noise (US) represents a stimulus with innate value. A conditioned stimulus (CS+) acquires value through consolidation of afferents, from sensory processing regions, to value systems through modulatory effects mediated by outputs from innately specified value systems.

How the brain processes fear-related visual stimuli

Innate salience or value refers to the ability of a stimulus to elicit emotional or adaptive responses in the absence of learning. Certain sensory stimuli, such as facial expressions that reflect basic emotions, are conjectured to possess innate salience or value determined by evolutionary selection (Darwin, 1965). Neuropsychological observations indicate a dissociation in processing facial identity involving extrastriate regions from regions involved in processing facial emotion (Young et al., 1993; Etcoff, 1984). Animal data suggest a role for the amygdala (and related subcortical structures) in emotional processing of faces (Rolls, 1995; LeDoux et al., 1990; LeDoux, 1993). Furthermore, human amygdala lesions lead to selective deficits in the recognition of fearful facial expressions (Adolphs et al., 1994; Calder et al., 1996) and impaired fear conditioning (Bechara et al., 1995; LaBar et al., 1995).

MEASURING NEURAL RESPONSES TO FEARFUL FACES
What brain systems process fear in facial expressions? To address this question we carried out an experiment, using functional neuroimaging, that compared neural responses of subjects as they viewed exemplars of either happy or fearful facial expressions. As well as representing distinct categories of expression we also introduced a parametric variation into the degree of emotion expressed in the stimuli by a computer graphical manipulation of the faces (Perrett, May, and Yoshikawa, 1994) (see figure 77.2A). The task requirement was for subjects to make a sex classification without any explicit instruction to attend to the facial expressions per se. Comparing the neural response associated with processing fearful and happy expressions revealed activation of left amygdala and left periamygdaloid cortex specific to the fear condition (see figure 77.2B) (Morris et al., 1996). Us-

ing similar stimuli, but without an intensity variation or a specific task instruction, these findings have now been replicated by others (Breiter et al., 1996). However, the introduction of an intensity variation allowed us to extend our analysis to describe brain regions conjointly responsive to emotion category (fearful versus happy) and expression intensity (low versus high). The data indicated that neural responses in the left amygdala increased monotonically with increasing intensity of expressed fear, as illustrated in figure 77.2C (Morris et al., 1996).

In terms of our model, processing innately fearful stimuli involves obligatory access to value- or fear-processing mechanisms. Because faces were classified by sex, and not by expression, we can infer that amygdala activation does not depend upon explicit hedonic processing of a target stimulus. The unilateral response, though surprising, parallels findings during procaine-induced fear (Ketter et al., 1996) and in patients with unilateral amygdala damage who show lower emotional intensity ratings for facial expressions in association with left- compared to right-sided amygdala lesions (Adolphs et al., 1995).

The neuromodulatory role of the amygdala in visual processing

Connections of the amygdala to sensory, motor, and autonomic output systems provide an anatomical basis for adaptive responses to stimuli that signal fear (Amaral and Price, 1984; Jones and Burton, 1976; LeDoux et al., 1988). This conjecture is reinforced by specific projections from amygdala to emotional processing regions such as orbitofrontal cortex, anterior cingulate cortex, ventral striatum, nucleus basalis, and brainstem nuclei (Jones and Powell, 1970; Amaral et al., 1992; Mesulam et al., 1983; Russchen, Amaral, and Price, 1985). The survival value conferred by adaptive responses to danger should provide mechanisms that enhance processing of salient, for example fear-provoking, stimuli (Friston et al., 1994; LeDoux, 1996). Our model of value-dependent learning proposes that engagement of value systems results in neuromodulatory effects that reinforce processing of salient cues. An important source of afferent inputs to primate amygdala is from temporal and early visual association cortices that represent distinct features of environment (Aggleton, Burton, and Passingaham, 1980; Iwai and Yukie, 1987). However, it is the more extensive amygdala efferents to early stages of visual processing that may, in part, mediate value-dependent neuromodulatory effects (Amaral and Price, 1984; Amaral et al., 1992; Iwai and Yukie, 1987).

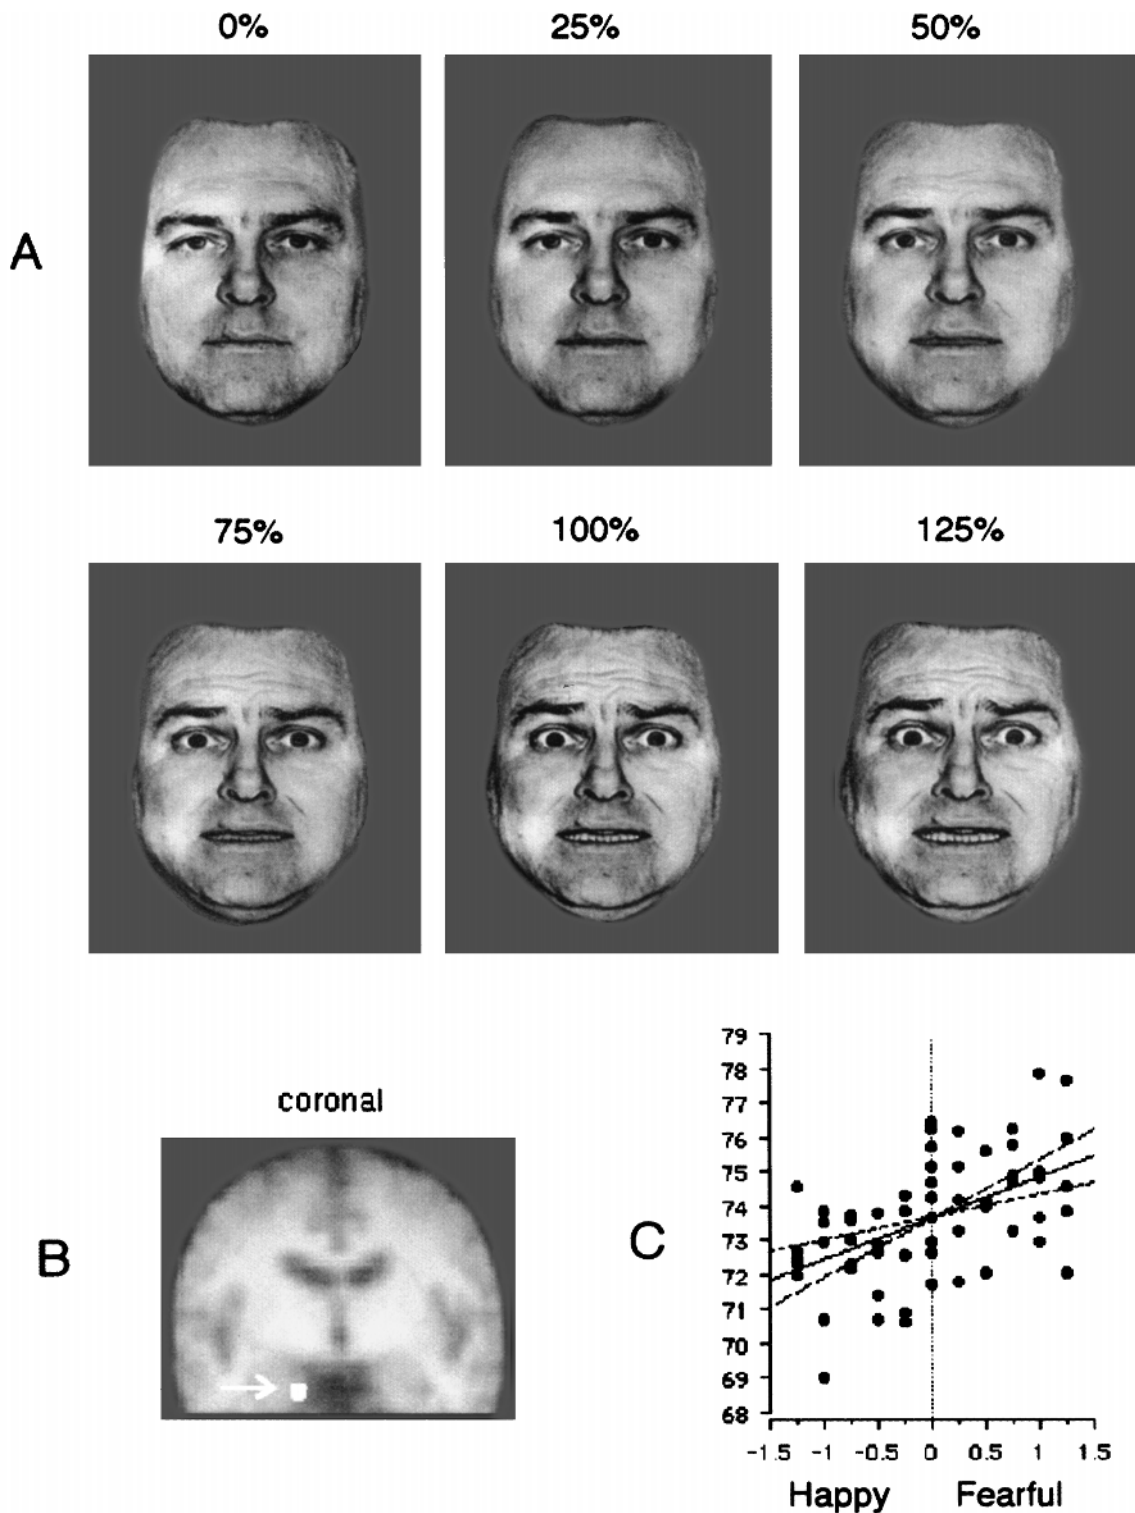

FIGURE 77.2 Fearful faces and the amygdala. (A) Different intensities of fearful expression produced by computer morphing. The 0% and 100% faces are prototypical neutral and fearful expressions, respectively. Faces 25%–75% are interpolations between these prototypes. The 125% face was created by shifting the shape of the fear prototype 25% further beyond 100% fearful. (B) The figure shows the left amygdala in which a significant area of activation is displayed on a coronal slice of a mean MRI image produced from all the subjects. (C) The

graph plots the regional cerebral blood flow (rCBF) values in milliliters per deciliter per minute for all conditions and all subjects at the pixel of maximal activation in the left amygdala. The x -axis represents the proportion of the prototypical expression in the face stimuli, with fearful being positive (i.e., 100% = 1) and happy negative (i.e., 100% = -1). A regression line has been fitted to the data, with broken lines representing the 95% confidence interval for the gradient of the slope.

CONTEXT-DEPENDENT NEURAL RESPONSES TO EMOTIONAL FACES To test a hypothesis that the amygdala selectively influences visual processing of salient stimuli, we examined its contribution to extrastriate activity under distinct psychological contexts (fear versus happy and vice versa). This approach is predicated on a concept of functional integration that emphasizes interactions between brain regions. The analysis involved measuring amygdala responses, under fearful and happy conditions, that are then regressed on activity in all other brain regions and directly contrasted using statistical parametric mapping (SPM) (Friston et al., 1997). What this type of analysis demonstrates is an aspect of effective connectivity between amygdala and other brain regions, where effective connectivity reflects “the influence one neural system exerts over another” (Friston, Frith, and Frackowiak, 1993). Strikingly, our analysis indicated an enhanced influence of the amygdala on extrastriate activity including bilateral inferior occipital gyri, right fusiform gyrus, and left lingual gyrus as well as the pulvinar, that was expressed solely during presentation of fearful stimuli (Morris, Friston, et al., 1998). Interestingly, the extrastriate regions with the strongest functional interactions with the amygdala subsume regions involved in face processing per se (Sergent et al., 1994; Dolan et al., 1997; Kanwisher, McDermott, and Chun, 1997). These context-dependent effects are illustrated in figure 77.3.

Processing salient visual stimuli

The behavioral values of sensory stimuli are not fixed but vary during the lifetime of an individual. Classical conditioning provides a simple model for this type of value-dependent learning. In essence, classical conditioning is a form of associative learning in which a neutral stimulus acquires value through close temporal pairing with an innately salient unconditioned stimulus. The amygdala is strongly implicated in this process with numerous studies highlighting dynamic changes in the interaction between auditory thalamus and amygdala during aversive noise conditioning (LeDoux, 1989, 1996). Neurobiological models have also proposed that the pulvinar may be crucial in early selective processing of salient sensory information (Olshausen, Anderson, and Van Essen, 1993), a proposal supported by electrophysiological recordings in monkeys (Robinson and Petersen, 1992).

CHANGES IN NEURAL RESPONSE TO FACES FOLLOWING CONDITIONING We used aversive classical conditioning to manipulate the behavioral significance of human facial expressions (happy, fearful, and neutral) while subjects underwent functional neuroimaging (PET). An ini-

FIGURE 77.3 The context-specific nature of the connectivity between the amygdala and a region of the extrastriate cortex is illustrated graphically. It can be clearly seen that the regression of amygdala responses on extrastriate cortex has a positive slope in the fearful condition (A) and a negative slope in the happy condition (B). This type of influence can be formulated in terms of a condition-specific change in the effective connectivity between brain regions.

tial question was which brain regions alter their responses when the behavioral relevance, but not other aspects, of a stimulus alters through learning. In the experiment subjects viewed a sequence of gray-scale images of faces consisting of two different faces, each repeated 8 times, presented in a pseudorandom order. Within a sequence the faces had either happy, fearful, or neutral expressions. Subjects responded “yes” if there was a consecutive repeat of a face and “no” if not. One face (the CS+) was always followed by a noise stimulus; the other face (the CS-) was always followed by silence. Scanning coincided with the end of the conditioning sequence and involved repeated presentations of one of the preceding faces in the absence of noise. In half the scans this face was a CS+, while in the other half the face was a CS-.

Contrasting all paired (CS+) with all unpaired (CS-) conditions highlighted right hemisphere activations in the pulvinar, orbitofrontal cortex, and superior frontal gyrus (Morris, Friston, and Dolan, 1997). The interaction between emotional expression and conditioning, which

tested for expression-specific activations, revealed augmented activation in the right pulvinar for happy expressions (see figure 77.4A). Activation of the right amygdala was also seen in the contrast of CS+ with CS– faces but at a lower significance than for the preceding activations. However, since this was the main predicted activation, the finding is nevertheless significant (see figure 77.4B). The overall findings accord with models that propose thalamic involvement in processing saliency within selected thalamocortical and corticothalamic circuits (Posner and Petersen, 1990; Petersen, Robinson, and Keys, 1985; Petersen, Robinson, and Morris, 1987; Robinson and Petersen, 1992; Rafal and Posner, 1989). The altered thalamic response reflects a form of stimulus-specific neural plasticity, where plasticity refers to experience-dependent changes in the physiological (hemodynamic) response to stimuli. Differential responses, elicited by the faces, were experience-dependent in the sense that they could only be explained by associative learning (prior to scanning). Recall that the only difference between the CS+ and CS– conditions was an experimental manipulation of salience. One question that arises concerns the mechanism of these experience-dependent changes in pulvinar response.

CHARACTERIZING FUNCTIONAL INTERACTIONS DURING CONDITIONING Our model of value-dependent learning predicts that connections to regions such as the amygdala from sensory processing systems are selectively strengthened when sensory stimuli acquire value (Friston et al., 1994). In the context of the outlined conditioning experiment, activity in the amygdala, and other “value systems,” should covary with thalamic activity during conditioning. The data accord with the prediction in that pulvinar activity, for all conditions expressed over the course of the entire experiment, showed significant covariation with activity in the right amygdala and basal forebrain regions (see figure 77.4C) (Morris, Friston, and Dolan, 1997). In this regard these functional neuroimaging findings complement animal data that stress the importance of thalamoamygdala interactions in emotional learning (LeDoux et al., 1990; LeDoux, 1995; Campeau and Davis, 1995; LeDoux et al., 1988; LaBar and LeDoux, 1996). However, it is important to emphasize that the analysis of covariation in our functional neuroimaging data does not speak to the directionality of influence between these regions.

Plasticity in sensory systems associated with emotional learning

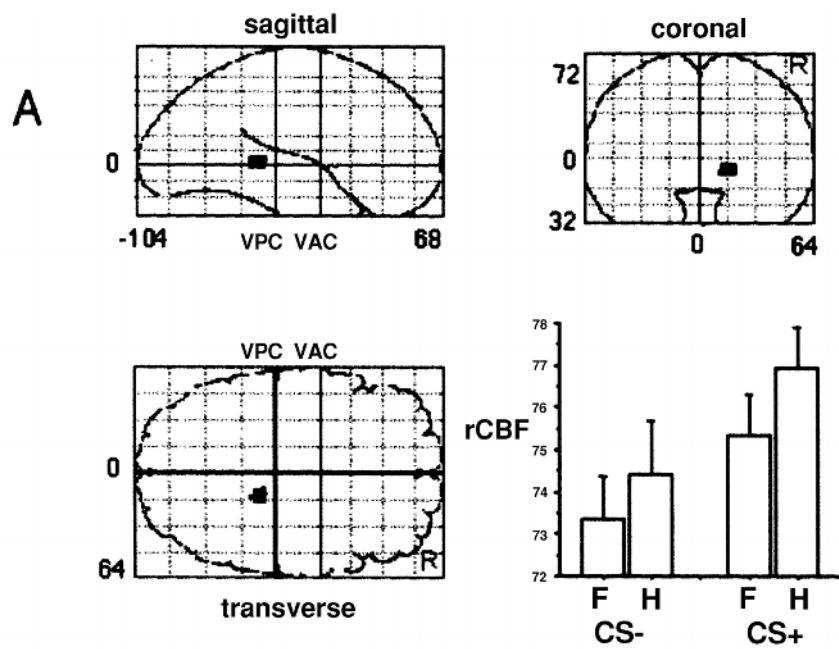

Emotional learning has been extensively investigated in animal models using electrophysiological methods. For

FIGURE 77.4 Aversive conditioning of faces. (A) Selective activation of the right pulvinar together with a graphical representation of the rCBF values. The SPM is the result of two orthogonal contrasts, the first selecting regions with a greater response to CS+ than CS– faces, and the second selecting voxels that responded more to happy expressions than fearful. The activation is displayed on a coronal slice of a canonical MRI image. The associated graph displays the adjusted mean activity (with bars showing 2 standard errors) for the right pulvinar. (B) Responses in the right amygdala, indexed by mean adjusted rCBF values for the CS+ and CS– conditions. (C) The regions that covary in response with activity in the pulvinar are shown superimposed on a structural MRI image. A, bilateral fusiform; B, hippocampus; C, right amygdala; D, medial forebrain; E, orbitofrontal cortex.

example, there is modulation of tonotopic auditory cortical responses when an animal learns, through conditioning, that an auditory stimulus predicts a future aversive event (Ashe, McKenna, and Weinberger, 1989; Edeline and Weinberger, 1991; Metherate and Ashe, 1991). This learning-related plasticity is dependent upon afferent inputs from medial geniculate nucleus (MGN) of thalamus, amygdala, and basal nucleus of Meynert (Weinberger, 1995). Little is known concerning the neural changes that ensue in the human brain consequent upon this type of emotional learning. It can be conjectured that the underlying mechanisms may be important in relation to psychopathological states such as phobias and posttraumatic stress disorder (PTSD).

THE PRIMARY AUDITORY CORTEX IN DISCRIMINATORY CONDITIONING To determine sensory changes associated with emotional learning, we used a discriminatory learning paradigm involving presentation of high-frequency (8000-Hz) and low-frequency (200-Hz) pure auditory tones. Three types of sequence were employed: *nonconditioning*, during which only pure tones were played; *unpaired* in which four 100-dB white-noise bursts (one second duration) were played midway between tones (equal frequency between low-high, high-low, high, and low consecutive tone pairs to ensure no differential conditioning to one frequency); and *conditioning*, in which four 100-dB white-noise bursts were played immediately after the offset of tones of one frequency to produce discriminatory classical conditioning to either high or low tones in a 4:10 partial reinforcement schedule. The tone frequency paired with noise represented the CS+; the tone frequency unpaired with noise was the CS–. An illustration of the experimental design is provided in figure 77.5.

Regions were first identified with tonotopic responses to the two distinct tone frequencies (200 Hz and 8000 Hz) independent of conditioning using nonconditioning sequence scans. Within these regions frequency-specific

modulation of neural responses occurred with discriminatory conditioning (see figure 77.6A). Surprisingly, these modulations all involved decreases in neural response to conditioned tone (CS+). In other words, there was an apparent attenuation of neural response of low-frequency-selective auditory cortex regions by association of low tones with an aversive noise. Responses to high tones were unaffected in this region. Modulations identical to those seen for low tones occurred in high-frequency-selective regions.

Reversals of frequency selectivity in auditory cortex parallel the experience-dependent receptive-field plasticity demonstrated in a range of animal species (Scheich et al., 1993; Recanzone, Schreiner, and Merzenich, 1993; Edeline and Weinberger, 1992; Weinberger and Diamond, 1987). In these experiments there is a small and narrowly tuned increase in response of auditory cortex for the CS+ frequency with decreased responses to surrounding frequencies (Edeline and Weinberger, 1992). The surprising frequency-specific attenuation of neural responses to CS+ tones may reflect these intrinsic lateral inhibition effects. Frequency-specific augmented responses are spatially restricted and likely to be masked by a greater surround inhibition. Within the spatial resolution of PET, this surround inhibition would result in an overall net decrease in activity. An alternative explanation is that a learned expectancy of noise, in relation to the CS+ tone, results in a generalized attentional inhibition of responses to the CS+ tone. A final possibility is that the block design, involving repeated nonpaired presentation of the CS+ within a scanning window, results in auditory response profiles that reflect extinction. Consistent with this explanation are studies of auditory conditioning that report decreases in auditory cortex activity during extinction (Molchan et al., 1994; Schreurs et al., 1997).

MGB AND PRIMARY CORTEX CONNECTIVITY DURING DISCRIMINATORY LEARNING In our model of value-dependent learning, stimuli that acquire salience are characterized by an ability to elicit responses in value systems. This effect occurs through a strengthening of connections between sensory systems and value systems. In auditory conditioning a crucial sensory processing region, in addition to primary auditory cortex, is the medial geniculate nucleus (MGN). When conditioning scans (CS+ and CS-) are contrasted with nonconditioning scans, increased activity is evident in a region of left inferoposterior thalamus that includes MGN and pulvinar. We reasoned that if conditioning-related modulation of auditory cortex responses was dependent on dynamic changes in the strength of inputs from MGN, then MGN activity should predict auditory cortex activ-

FIGURE 77.5 Diagrammatic representation of stimulus sequences in an auditory conditioning experiment. (A) A non-conditioning sequence during which no noises are played. (B) An unpaired sequence, identical to A, except that noise bursts are played midway between tones. (C) A conditioning sequence, identical to A and B, except that the noise bursts occur immediately following high-frequency tones. Note that noises never occur in any of the scanning windows (indicated by boxes). H, high-frequency tones; L, low-frequency tones; N, noise-burst.

ity under the context of conditioning (compared to non-conditioning). As illustrated in figure 77.6B, the MGN contribution to activity in auditory cortex is significantly greater for the conditioning than nonconditioning sequences. This finding indicates that context-dependent alterations in the effective connectivity between MGN and auditory cortex accompany processing of stimuli with adaptive value (Friston et al., 1997). The similarity between conditioning-related dynamic interactions between MGN and auditory cortex in animals and humans is striking (McIntosh and Gonzalez-Lima, 1995).

*Studying emotional learning with fMRI:
An event-related approach*

Studies using PET and fMRI have been limited by a necessity to use blocked designs in which target stimuli are repeatedly presented. In a typical experiment subjects are conditioned during one block by presenting a CS with a US and neural responses assessed in a second block when the CS is presented alone (Morris, Friston, and Dolan, 1997). However, this procedure is confounded by the fact that the second block, when a CS is presented alone, must reflect extinction as much as emotional learning. This distinction is critical given evidence that the neural systems implicated in learning acquisition and extinction differ (Rolls et al., 1994).

The optimal conditions to study emotional learning are met by event-related fMRI (Buckner et al., 1996; Dale and Buckner, 1997; Josephs, Turner, and Friston, 1997). This technique is similar to event-related potential

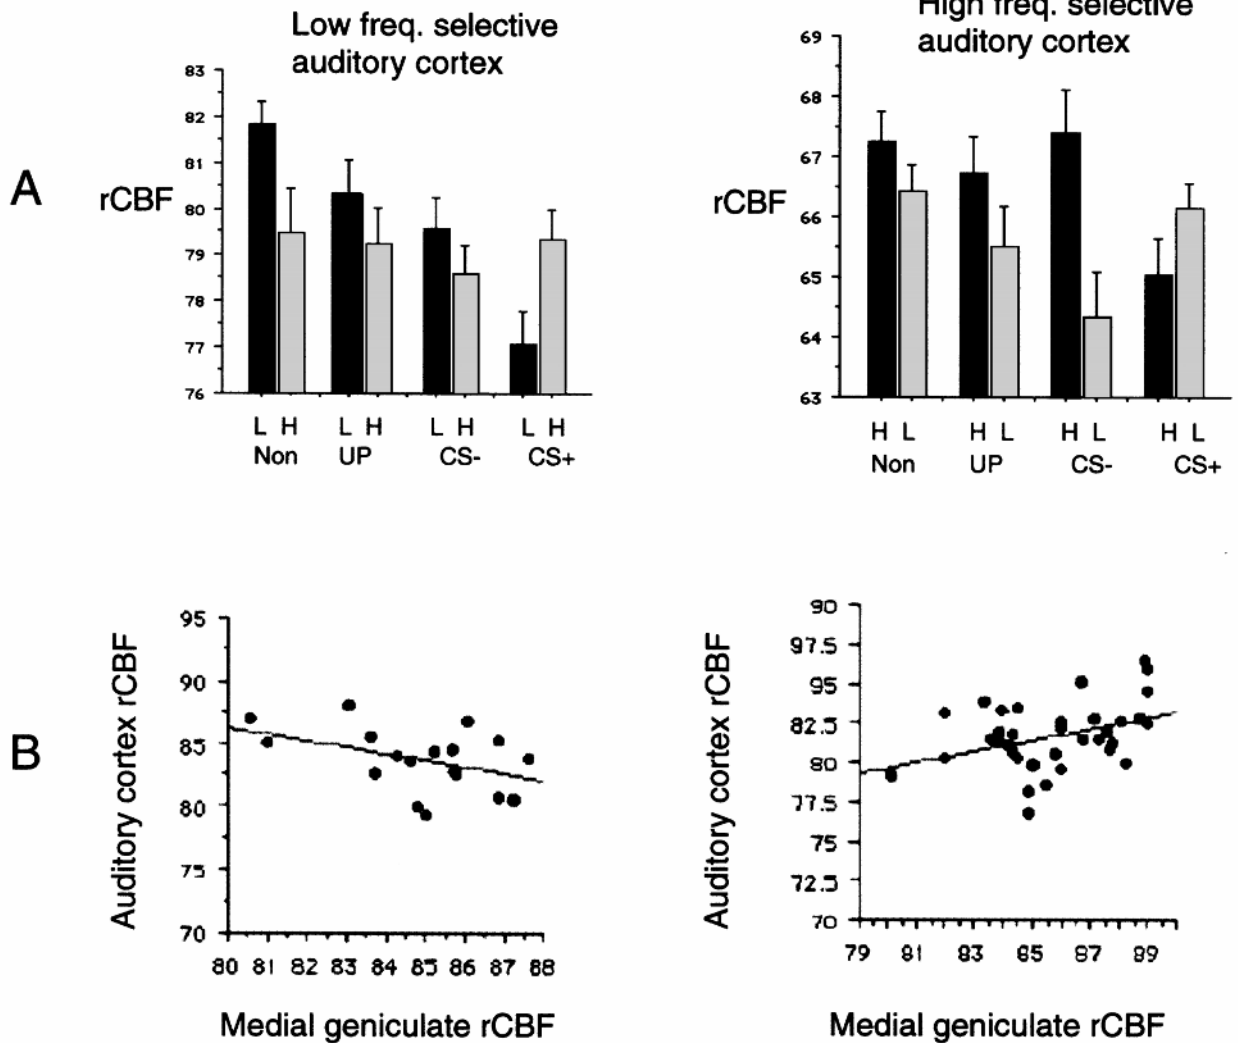

FIGURE 776 Learning-related modulation of auditory cortex. (A) Graphical displays of mean rCBF values for voxels in left auditory cortex with a selectivity for low-frequency and high-frequency tones. L, low-frequency tones; H, high-frequency tones; Non, nonconditioned scans; UP, scans in which both tone frequencies were unpaired with noise; CS+, scans in which the tone frequency associated with noise was presented; CS-, scans

in which the tone frequency explicitly not associated with noise was presented. (B) Bivariate regression plots of rCBF values (in ml/dl/min) in auditory cortex ($x = -50$, $y = -12$, $z = -4$) and medial geniculate nucleus ($x = -12$, $y = -26$, $z = -2$) for conditioning and nonconditioning scans. Note the context-specific positive slope for conditioning and negative slope for nonconditioning sequences.

recordings in electrophysiology where responses to different stimuli are individually sampled and subsequently averaged. Recent technical advances have enabled a study of evoked hemodynamic responses for the whole brain, to conditioned and neutral reference stimuli, in a manner applicable to mixed-trial classical conditioning paradigms (Josephs, Turner, and Friston, 1997). In contrast to evoked responses in electrophysiology, the sampling rate (i.e., TR) in event-related fMRI is restricted. Consequently, to characterize hemodynamic responses to a target stimulus, it is necessary to sample data points after the onset of many stimuli at different peristimulus time points. This purpose can be achieved by the intro-

duction of a fixed or random jitter between the inter-stimulus interval (ISI) and TR.

MEASURING SINGLE NEURONAL RESPONSES DURING EMOTIONAL LEARNING To assess neural responses to single events we chose four neutral faces, two male and two female from the Ekman series, as target stimuli (Ekman, 1982). Subjects were scanned during two distinct phases. During conditioning two of the four faces (one male, one female) were paired with an unpleasant tone, lasting 500 ms and adjusted to 10% above each subject's pain threshold, to become CS+. To assess evoked hemodynamic response to the CS+ in the absence of the

FIGURE 77.7 Single-event fMRI and conditioning. The figure describes the experimental design in which four images of faces were presented to subjects. Two faces were conditioned with an aversive tone using a 50% partial reinforcement schedule (i.e., half the presentations were followed by an aversive tone). Vertical dotted and dashed lines indicate the onset of the

visual and auditory stimulus, respectively. The time course plots show the corresponding modeled hemodynamic responses time-locked to the onset of the face stimuli (CS-, unpaired CS+, and paired CS+). The time scale indicates that the ISI was randomized to introduce a phase shift between sampling and stimuli onset.

US (i.e., tone) a 50% partial reinforcement strategy was employed. In effect only half the presentations of the two CSs were paired with the tone. In total, 104 stimuli were presented over a period of approximately 20 minutes. Of these, 52 were neutral stimuli, 26 were CS paired with noise, and 26 were CS not paired with noise. Figure 77.7 provides an illustration of the experimental design.

Four event types were defined, three of which were time-locked to the onset of the presentation of the face and the fourth to the onset of the tone (Buechel et al., 1998). The three visual events were subdivided into (1) CS-, (2) CS+ unpaired, and (3) CS+ paired face stimuli (first three rows in figure 77.7). The comparisons of interest were between conditioning-evoked neural re-

sponses to the unpaired CS+ (i.e., no noise presentations) and the CS-. Differential activation of anterior cingulate gyrus and bilateral anterior insular cortex were seen for the CS+ conditions (figure 77.8; see color plate 47). Other differential responses, of lesser significance, were detected in motor output regions including the supplementary motor area (SMA), the left premotor cortex, and both red nuclei. Overall, these data implicate an extended neural system that includes insula as well as motor output regions, such as SMA, cingulate, and red nuclei in emotional learning.

The most robust activations were located in bilateral cingulate and insular cortices. The cingulate is a functionally heterogeneous region with known roles in regulating context-dependent behavior (Devinsky and

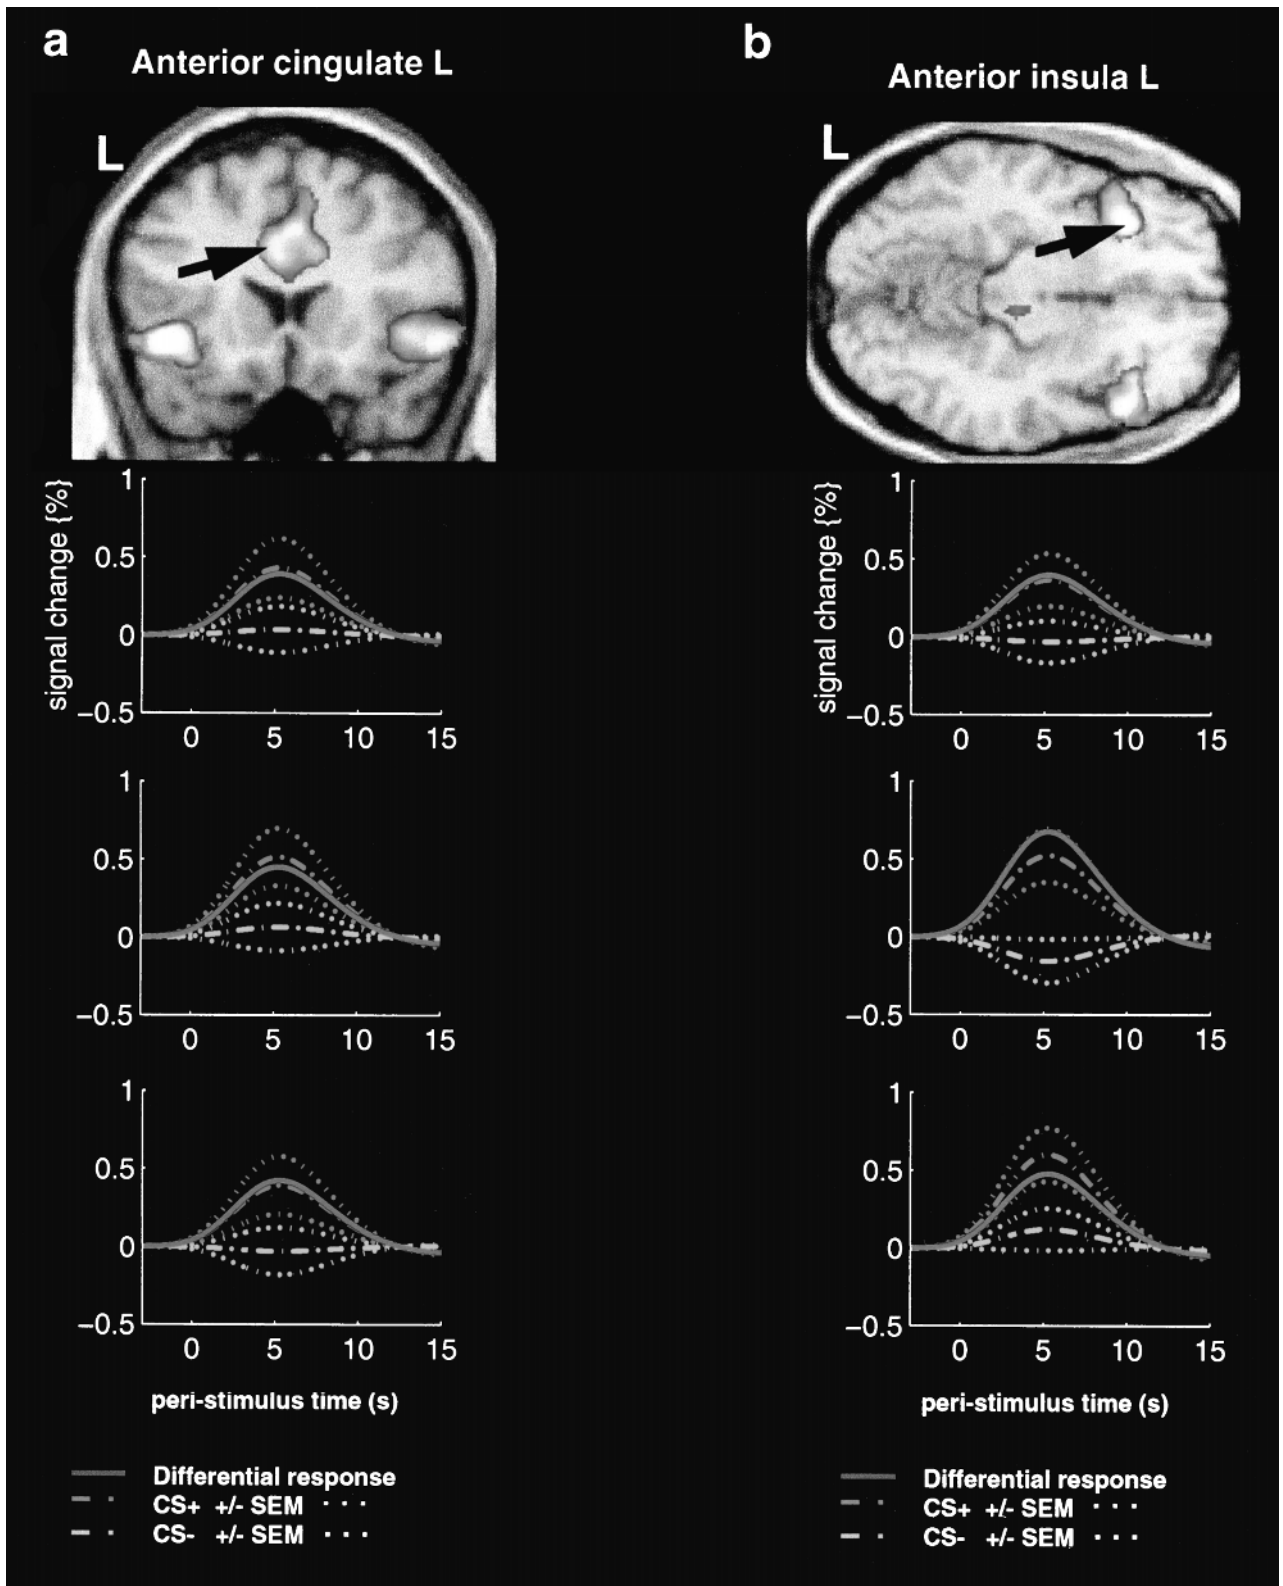

FIGURE 77.8 Averaged single event responses during acquisition. The top of the figure shows the focus of significant differential activations ($CS+ > CS-$) in anterior cingulate (circled) and bilateral anterior insula superimposed on a structural MRI scan. At the bottom the peristimulus time plots for all 6 subjects are displayed with reference to differential cingulate responses.

The plots show the fitted response \pm the standard error of the mean (SEM) for $CS-$ (blue) and unpaired $CS+$ (red) events. Dashed lines correspond to mean responses, and dotted lines are SEM. Statistical inference is based on the difference between the two responses, which is shown in green.

Luciano, 1993). Activation in a similar region has been reported in association with processing the affective component of painful stimuli (Rainville et al., 1997). Its activation with presentation of CS+ may reflect a predictive function with respect to the probability of occurrence of a future aversive event. Alternatively, its engagement may reflect adaptive sensorimotor responses to salient stimuli with activation of brainstem nuclei (red nuclei) reflecting a more downstream component. This latter region is also implicated in animal and human eye-blink conditioning paradigms (Logan and Grafton, 1995; Clark and Lavond, 1993; Desmond and Moore, 1991). The other highlighted region was the anterior insula. This is an area with projections to anterior cingulate, perirhinal, entorhinal, and periamygdaloid cortex and various amygdaloid nuclei that has led to its conceptualization as an area functionally associated with emotional processing (Augustine, 1996). Its strong connections to sensory regions may mean that its activation reflects changes in the bodily state that anticipate adversity, in this case an unpleasant noise (Mesulam and Mufson, 1982). In terms of our model the insula may mediate interoceptive inputs to value systems that reflect anticipatory homeostatic changes. Several functional neuroimaging studies suggest a role for the anterior insula in processing emotional contexts, for example pain (Casey et al., 1994) or the recollection of affect-laden autobiographical information (Fink et al., 1996). The mnemonic component of our study is that the CS+ is predictive of a future unpleasant sensory event (US).

Surprisingly, amygdala responses were not found in a categorical comparison of neural responses to a CS+ versus a CS-. One possible explanation is that amygdala response shows rapid habituation during emotional learning as indicated in animal experiments (Breiter et al., 1996). Temporal effects, where the magnitude of response changes over time, would not be revealed in a simple categorical analysis and need to be explicitly tested for using time-by-event-type interactions. In effect these test for areas in which neural responses to a CS+ decrease over time, and at the same time this pattern is significantly different for responses evoked by the CS-. In this analysis there were significant differential adaptations evident for the CS+ relative to the CS-, indicating rapid habituation of amygdalae responses for the CS+ that were significant for bilateral amygdalae (see figure 77.9). These data are remarkably similar to those seen in animal classical conditioning (Bordi et al., 1993; Quirk, Armony, and LeDoux, 1997) and neuroimaging experiments from other groups (LaBar et al., 1998). The transient response profile of the amygdala suggests a role in early phases

of emotional learning. A similar early versus late dissociation during learning suggested for the hippocampus may also apply to the amygdala.

Conscious awareness and processing of learned fear

Ekman, in proposing the concept of affect programs, had little to say concerning their neurophysiological implementation. However, he was explicit in proposing that some elicitors "will activate the facial affect program with little or no prior cognitive processing" (Ekman, 1971). Important empirical research, consistent with this conjecture, includes evidence of discriminatory skin conductance responses (SCRs) to aversively conditioned stimuli that have been backwardly masked to prevent conscious awareness of their occurrence (Esteves, Dimberg, and Öhman, 1994; Öhman and Soares, 1994; Parra et al., 1997). An intriguing neurobiological question is how, in the absence of conscious awareness, the brain discriminates between physically equivalent stimuli when one of the stimuli has acquired salience through prior learning. A related question is whether level of awareness of an emotionally salient stimulus modulates the associated neural processing.

The ability of the brain to discriminate between salient stimuli without conscious awareness provides evidence that, in certain contexts, processing of inputs to value systems may be obligatory. It has been proposed that an integrated response to threat or danger, without higher level processing, can be mediated via the amygdala (Kling and Brothers, 1992) or thalamic-amygdala circuitry (LeDoux, 1996). In terms of emotional learning, patients with amygdala damage fail to acquire conditioned SCRs to stimuli paired with an aversive unconditioned stimulus (US) despite intact declarative knowledge concerning stimulus associations (Bechara et al., 1995; LaBar et al., 1995). Conversely, patients with intact amygdalae and damaged hippocampi acquire reliable discriminatory SCRs but cannot report which stimuli have been paired with the UCS (Bechara et al., 1995). The role of the amygdala is also highlighted by functional neuroimaging data (fMRI) where discriminatory responses to masked fearful and happy faces have been demonstrated in the absence of explicit awareness of their occurrence (Whalen et al., 1998).

CONSCIOUS AND UNCONSCIOUS PROCESSING OF FEARFUL FACES To determine how the brain discriminates between salient stimuli in the absence of conscious awareness, we used a backward masking procedure involving presenting targets on a screen for 30 milliseconds immediately followed by a masking stimulus for 45 milliseconds (Morris, Öhman, and Dolan, 1998). This

FIGURE 77.9 (a) Bilateral activation of amygdalae for an analysis based on a time-by-condition (CS+ versus CS-) interaction. (b and c) Fitted responses for CS+ in the left amygdala from two individual subjects. It can be seen that responses are initially positive and then attenuate to become relative deactivations (relative to baseline). (d) Differences in SCRs for CS+ and CS- for first 8 minutes and last 12 minutes of conditioning corresponding to scanning data. This interaction between early and late phases is significant and mirrors that seen for the amygdala response in terms of early and late components.

procedure effectively prevents reportable awareness of the target stimulus (see figure 77.10A). Faces were again used and consisted of two angry and two neutral expressions. In a conditioning study phase, one of the angry faces (the CS+) was paired with a 1-second 100-dB white-noise burst. None of the neutral faces was ever paired with noise. During scanning, faces consisting of a target and mask were repeatedly shown at 5-second intervals for each experimental condition. In effect, for half the experimental conditions, subjects' awareness of the target angry faces, conditioned and unconditioned, was prevented by masking with neutral faces (see figure 77.10B). The subject's task was to report, by pressing a button, the occurrence of an angry face. The factorial design of the experiment is outlined in figure 77.10C.

Behaviorally, none of the angry faces were reported in the masked condition, whereas the detection rate of unmasked angry faces was 100%. Mean SCRs were significantly greater for CS+ than CS- faces, both for masked and unmasked presentations. Contrasting all CS+ (masked and unmasked) with all CS- scans (masked and unmasked) revealed bilateral amygdala responses. When neural responses to unmasked CS+ and CS- faces were contrasted, a significant response was evident in the region of the left amygdala (see figure 77.10D). To determine whether this amygdala response also occurred when subjects were not aware of the conditioned faces, we contrasted masked CS+ and CS- scans. This comparison revealed a highly significant effect in the right amygdala (see figure 77.10E). The interaction between conditioning and masking indicated that the right amygdala response to CS+ faces is significantly enhanced by masking while the left amygdala response is enhanced by unmasking. Note again that the only difference between the CS+ and CS- conditions was subjects' prior experience of the temporal association between CS+ faces and an aversive noise.

Two general conclusions can be drawn from these data. First, they indicate that the amygdala discriminates between perceptually similar stimuli solely on the basis of their prior history. This discrimination (at least for the right amygdala) occurs without conscious awareness of a

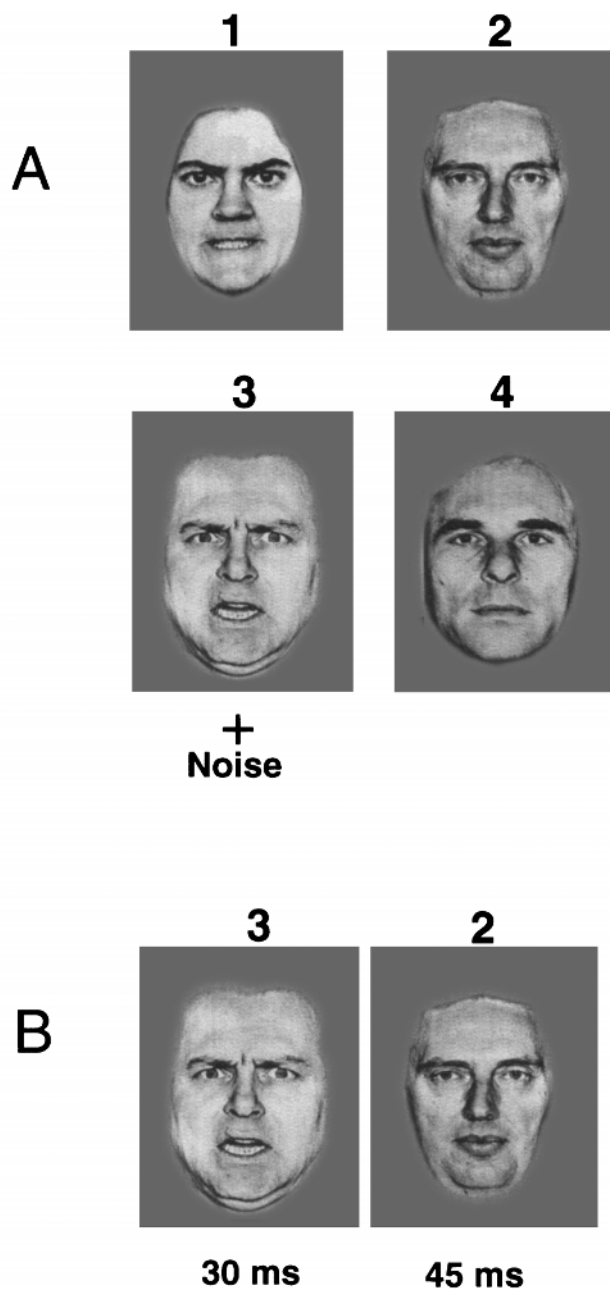

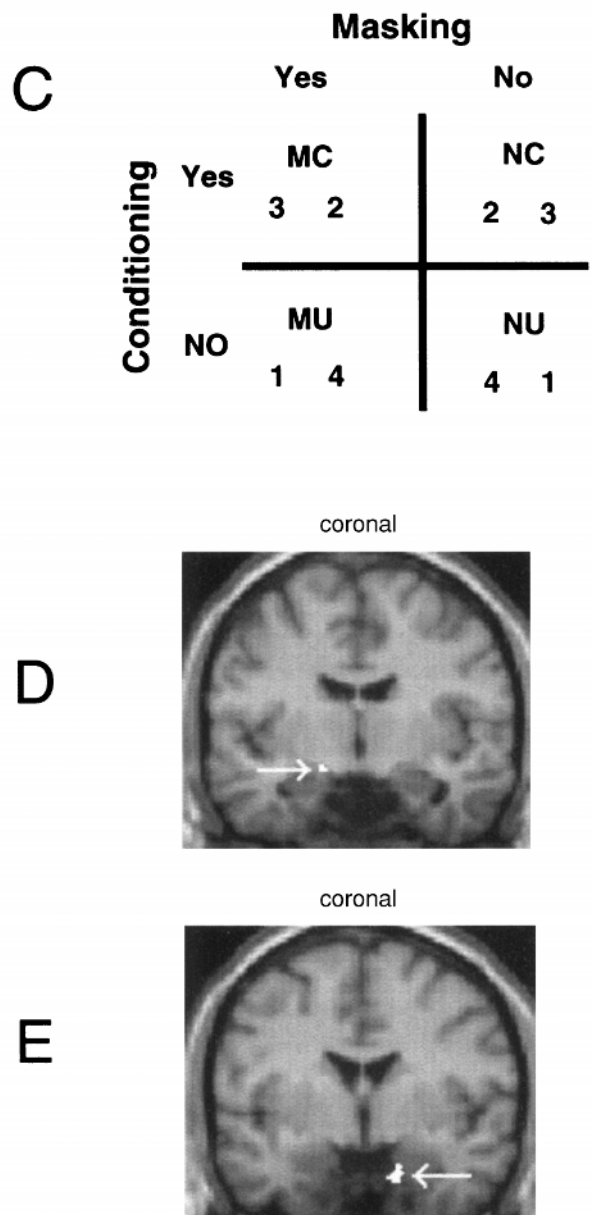

FIGURE 77.10 Masking of aversively conditioned faces. (A) In a prescanning conditioning sequence, 2 angry faces (1 and 3) and 2 neutral faces were shown sequentially for 75 ms at 15–25-s intervals. One of the angry faces (3) was always followed by a 100-dB white-noise burst. (B) During scanning, 2 faces were shown in rapid succession to produce backward masking of the first face by the second. In all conditions, the target face was displayed for 30-ms and immediately followed by a 45-ms

target stimulus. These data also extend functional neuroimaging findings that the amygdala can discriminate between salient, but categorically distinct, facial emotions (Whalen et al., 1998). The data also provide a

mask. (C) There were 4 separate conditions, determined by whether the angry face was masked or conditioned. MC, masked conditioned; NC, nonmasked conditioned; MU, masked unconditioned; NU, nonmasked unconditioned. (D) The figure shows activation of left amygdala in the contrast of unmasked CS+ and CS– angry faces displayed on a coronal slice of a group averaged MRI image. (E) Activation of right amygdala in the contrast of masked CS+ and CS– angry faces.

mechanistic account of behavioral observations that indicate unconscious processing of previously learned aversive stimuli (Esteves, Dimberg, and Öhman, 1994; Öhman and Soares, 1994; Parra et al., 1997). Second,

the pattern of lateralization is modulated by reportable awareness of the target stimulus. This finding suggests that factors related to conscious awareness, for example automatic engagement of language systems, influence processing of salience. "Split-brain" patients can verbally report stimuli shown to the isolated left hemisphere but deny awareness of the same stimuli presented to the right hemisphere (Gazzaniga, 1989). Conversely, the isolated right hemisphere shows superior performance in tasks involving facial and emotional processing (Gazzaniga, 1989; DeKosky et al., 1980). The lateralized amygdala responses indicate that the same segregation of reportable and unreportable processing observed in split-brain subjects is also manifest in the intact brain.

Conclusions

The account of emotional processing outlined has focused on a primary emotion, fear. A critical role for the amygdala is highlighted in discriminating between stimuli that represent danger and during emotional learning. Discriminatory emotional learning is associated with neural plasticity in primary sensory regions and changes in afferent connection strengths to these regions. The response profile of the amygdala, during emotional learning, is complex and is best characterized in terms of time-dependent changes involving early activation and late deactivations. The amygdala's role in processing behaviorally relevant stimuli would seem to be automatic and obligatory in that its response can discriminate between the behaviorally relevant sensory inputs independent of conscious awareness.

78 Posttraumatic Stress Disorder: Emotion, Conditioning, and Memory

ROGER K. PITMAN, ARIEH Y. SHALEV, AND SCOTT P. ORR

ABSTRACT Posttraumatic stress disorder (PTSD) provides illustrations of human mechanisms of emotion, conditioning, and memory that can inform cognitive neuroscience. Because the etiologic event can be clearly identified, the role of Pavlovian conditioning is clearer in PTSD than in other mental disorders. Laboratory studies have confirmed the presence of peripheral physiologic reactivity upon exposure to internal or external cues that symbolize or resemble an aspect of the traumatic event in PTSD. Functional neuroimaging studies implicate the anterior paralimbic system, including the amygdala, as a key brain area in the formation and elaboration of posttraumatic conditioned fear responses. In contrast, structural neuroimaging and functional memory studies suggest posterior paralimbic (i.e., hippocampal) impairment in PTSD. Persons with PTSD appear to be more conditionable on a constitutional or acquired basis. They are also more reactive to non-conditioned, especially startling, stimuli. Facilitation of emotional memory by stress hormones (especially epinephrine) released at the time of the traumatic event is theoretically involved in the pathogenesis of PTSD.

Because psychopathologic phenomena often represent extreme forms of ordinarily adaptive human behavior, evolutionary neurobiologic mechanisms may be cast in higher relief in the mentally disordered. Darwin (1872) noted that the behavior of insane patients reveals the “brute nature” within human beings. Behavior associated with mental disorders constitutes potentially useful data that are often overlooked by basic scientists.

The recently rediscovered mental disorder known as posttraumatic stress disorder (PTSD) provides illustrations of human mechanisms of emotion, conditioning, and memory that can inform cognitive neuroscience. This chapter will examine some examples. Comprehensive reviews of the neurobiology of PTSD have appeared elsewhere (Friedman, Charney, and Deutch, 1995; Yehuda and McFarlane, 1997).

PTSD and conditioned fear

The current clinical definition of PTSD according to the *Diagnostic and Statistical Manual of Mental Disorders*, 4th ed. (DSM-IV; American Psychiatric Association, 1994) appears in abbreviated form in table 78.1. Readers of this chapter will readily recognize the basic elements of classical (or Pavlovian) conditioning that it incorporates. After a traumatic event (unconditioned stimulus, or UCS) has induced an intense emotional response of fear, helplessness, or horror (unconditioned response, or UCR), external and internal cues that were present at the time of the traumatic event (conditioned stimuli, or CSs) acquire the capacity through their association with the traumatic experience to evoke intense emotional responses (conditioned responses, or CRs) on subsequent occasions. Avoidance of emotionally distressing and arousing trauma-related cues reflects secondary operant conditioning.

In addition to the specific symptoms of PTSD (B.1–5, C.1–3 in table 78.1) that are related to conditioning and uniquely define this disorder, there are several general psychiatric symptoms (C.4–7, D.1–4) that PTSD shares with other anxiety and/or depressive disorders.

PERIPHERAL PHYSIOLOGIC RESPONSES TO TRAUMA-RELATED CUES DSM-IV PTSD criterion B.5, “physiological reactivity upon exposure to internal or external cues that symbolize or resemble an aspect of the traumatic event,” has been amply supported in the laboratory. Several studies have shown that audiovisual cues of battle situations (e.g., pictures of ground troops unloading from helicopters, sounds of machine gun fire) produce larger increases in heart rate (HR) and blood pressure (BP) in veterans with PTSD (reviews in Blanchard, 1990; Orr, 1994; Shalev and Rogel-Fuchs, 1993). McNally and colleagues (1987) reported larger skin conductance (SC) responses to combat-related words in Vietnam veterans with PTSD.

When individuals with PTSD have recalled past traumatic events via internal, script-driven imagery, they have produced larger HR, SC, and facial electromyogram

TABLE 78.1
Abridged DSM-IV diagnostic criteria for PTSD (American Psychiatric Association, 1994)

-
- A. Traumatic event/response
 - 1. An event that threatens or inflicts serious injury to self or others
 - 2. A response of intense fear, helplessness, or horror
 - B. Reexperiencing criteria (one required)
 - 1. Recurrent, intrusive, distressing recollections of the traumatic event
 - 2. Recurrent, distressing dreams of the traumatic event
 - 3. Flashbacks to the traumatic event
 - 4/5. Intense psychological distress/physiological reactivity on exposure to traumatic event-related cues
 - C. Avoidance/numbing criteria (three required)
 - 1. Of thoughts and feelings associated with the trauma
 - 2. Of activities, places, or people associated with the trauma
 - 3. Inability to recall an important aspect of the trauma
 - 4. Markedly diminished interest in significant activities
 - 5. Feelings of detachment or estrangement from others
 - 6. Restricted range of affect (numbing)
 - 7. Sense of a foreshortened future
 - D. Arousal criteria (two required)
 - 1. Insomnia
 - 2. Irritability or outbursts of anger
 - 3. Difficulty concentrating
 - 4. Hypervigilance
 - 5. Exaggerated startle response
 - E. Duration at least one month
 - F. Distress/impairment, e.g., social, occupational
-

(EMG) responses than individuals who experienced similarly stressful events but did not develop the disorder (review in Orr, 1994). This finding has held for various types of traumatic events including combat in Vietnam (Pitman et al., 1987), Korea, and World War II (Orr et al., 1993); terrorist attacks and other traumatic events (Shalev, Orr, and Pitman, 1993); and childhood sexual abuse (Orr, Lasko, et al., 1998), all of which were studied under similar laboratory conditions using the same script-driven imagery technique (figure 78.1). The finding has also been replicated for PTSD resulting from motor vehicle accidents (Blanchard et al., 1996). Results of a large multisite study of 1328 Vietnam veterans that combined audiovisual cues and script-driven imagery (Keane et al., 1998) found heightened physiologic reactivity to trauma-related cues in the veterans with PTSD.

If classical conditioning is the mechanism by which emotional responses to trauma-related cues are acquired, then reactivity should be specific to trauma-related stimuli. Such specificity is supported by findings of comparable autonomic reactivity between PTSD and non-PTSD subjects to imagery of stressful life events unrelated to the event that caused the PTSD (Orr et al., 1993; Pitman et al., 1987; Shalev, Orr, and Pitman, 1993) and to mental arithmetic and other generic stressors (Blanchard et al., 1986; Orr, Meyerhoff, et al., 1998).

STRESS-INDUCED ANALGESIA Exposure to previously conditioned fear stimuli has been shown to produce analgesia in animals (Fanselow, 1986). In many instances, this effect is reversed or blocked by the opiate antagonists naloxone and naltrexone. If the emotional responses generated by trauma-related cues in PTSD veterans represent conditioned fear, then combat-related stimuli might be expected to produce an analgesic response in the laboratory. This expectation was tested in a study of eight Vietnam veterans with PTSD and eight non-PTSD veterans that measured pain responses to standardized heat stimuli after exposure to a videotape of dramatized combat in Vietnam. Subjects previously received either naloxone or placebo in a randomized, double-blind, crossover design (Pitman, van der Kolk, et al., 1990). Consistent with the hypothesis, PTSD subjects after viewing the combat videotape showed a 30% decrease in pain intensity ratings after receiving placebo but no decrease after naloxone. The non-PTSD subjects showed no decrease in pain ratings in either condition. Interestingly, degree of control over the stressful event has been found to mediate both stress-induced analgesia (Maier, 1986) and PTSD (Kushner et al., 1993).

TRAUMA-RELATED PET ACTIVATION STUDIES Recent studies of PTSD using positron emission tomography (PET) have more directly examined changes in brain

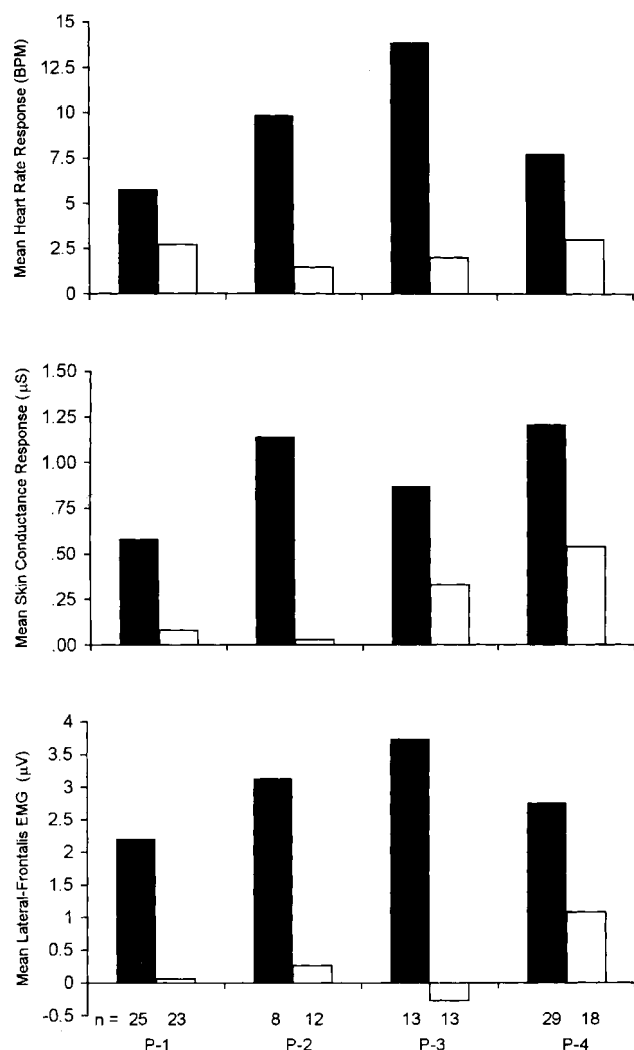

FIGURE 78.1 Physiologic responses during personal, script-driven, traumatic imagery of subjects with (black bars) and without (white bars) posttraumatic stress disorder recruited from various trauma-exposed populations. P = 1, male Vietnam combat veterans (Pitman et al., 1987; Pitman, Orr, et al., 1990); P = 2, male World War II and Korean combat veterans (Orr et al., 1993); P = 3, male and female Israeli civilian trauma victims (Shalev, Orr, and Pitman, 1993); P = 4, female victims of childhood sexual abuse (Orr, Lasko, et al., 1998). BPM, beats per minute; μS , microsiemens; μV , microvolts; EMG, electromyogram.

activity that presumably underlie emotional reexperiencing in PTSD. Rauch and colleagues (1996) employed personal script-driven imagery to study eight individuals with PTSD (six women and two men) stemming from a variety of traumatic events. During traumatic imagery compared to neutral imagery, there were significant increases in regional cerebral blood flow (rCBF) in anterior paralimbic structures, including posterior medial orbitofrontal, insular, anterior temporal, medial temporal, and anterior cingulate cortex, as well as amygdala (figure 78.2; see color plate 48). An rCBF decrease was found in

Broca's area. However, because this study included neither non-trauma-related scripts nor a non-PTSD comparison group, it was not possible to determine the specificity of the findings to trauma-related stimuli or PTSD.

Shin, Kosslyn, and colleagues (1997) examined rCBF during PET in seven PTSD and seven non-PTSD Vietnam combat veterans during exposure to combat pictures and during imaginary recall of the same pictures. Increased rCBF was found in anterior cingulate cortex and amygdala in PTSD subjects, but not in non-PTSD subjects, during imagery of the combat pictures. Interestingly, imagery was more effective than direct perception in activating anterior paralimbic areas.

Recently, Shin, McNally, and colleagues (1999) examined rCBF during script-driven imagery in 16 women with histories of childhood sexual abuse, eight with PTSD, and eight without PTSD. Subjects with PTSD showed significantly greater activation than non-PTSD subjects during personal sexual abuse imagery compared to neutral imagery in orbitofrontal cortex and anterior temporal pole. Anterior cingulate cortex, however, was differentially activated in the non-PTSD group. The PTSD group showed a significantly greater deactivation of Broca's area. With the exception of anterior cingulate cortex, these results are consistent with the aforementioned studies regarding the role of anterior paralimbic regions in the mediation of emotional responses during imagery of traumatic events in PTSD. There were no significant activation peaks localizable to amygdala within either group.

In summary, PET activation studies converge to show increased activation of orbitofrontal cortex and anterior temporal pole, and decreased activation of Broca's area, during exposure to trauma-related cues in individuals with PTSD. Absence of amygdala activation in some studies could reflect technical difficulties in capturing rCBF changes in this small structure. Alternately, it might be that the amygdala is more critical in the acquisition of conditioned fear responses than in their later evocation. Findings from studies of normal humans have been inconsistent on this question (Hugdahl, 1998; Morris, Öhman, and Dolan, 1998).

BASIC CONDITIONING RESEARCH RELEVANT TO PTSD

In animal work, LeDoux (1996) has shown that connections from the thalamus to the amygdala constitute a "quick and dirty" pathway for the mediation of conditioned fear. The thalamocorticoamygdala pathway is a parallel system that allows more precise but slower elaboration and discrimination of sensory input. LeDoux has found that lesions of the thalamoamygdala connection prevent the acquisition of conditioned fear

FIGURE 78.2 Positron-emission-tomography statistical parametric map of regional cerebral blood flow during traumatic minus neutral personal imagery in eight subjects with post-traumatic stress disorder, displayed with a Sokoloff color scale in units of z score. White dashed outlines reflecting the boundaries of specified brain regions, as defined via a digitized version of the Talairach atlas, are superimposed for ana-

tomic reference. Whole-brain slice outlines are demarcated with solid lines. The transverse section shown is parallel and 12 mm inferior to the intercommissural plane. Top, anterior; bottom, posterior; right, left; left, right. responses. In contrast, certain lesions of medial prefrontal cortex in rats (roughly corresponding to anterior cingulate cortex in humans) enhance the acquisition and/or retard the extinction of such responses (Morgan and LeDoux, 1995), implying that intact cortex inhibits acquisition and facilitates extinction. This pattern of findings suggests that extinction of conditioned emotional responses does not involve their undoing, but rather the superimposition of cortical inhibition on their behavioral expression. When this inhibition fails, the conditioned responses are there waiting to emerge. In

humans, medial temporal lesions (LaBar et al., 1995), amygdala lesions in particular (Bechara et al., 1995), are associated with deficits in aversive electrodermal conditioning.

This research has led to the conclusion that once formed, "emotional memory may be forever" (LeDoux, 1990, p. 41). Posttraumatic stress disorder may represent an unhappy clinical manifestation of this proposition. The concept of indelible subcortical conditioned emotional responses, held in check with varying degrees of success by the cortex, can account for several

clinical observations in PTSD. For example, delayed-onset PTSD, recognized in the DSM-IV, may represent the activated expression of latent conditioned fear responses upon the failure, for whatever reason, of cortical inhibitory control. Also, PTSD patients in clinical remission are vulnerable to the effect of further stress and may relapse upon exposure to it (Solomon et al., 1987). The prediction of a higher occurrence of PTSD in Vietnam veterans at times when their psychological defenses are compromised (Horowitz and Solomon, 1975) is in line with this viewpoint, as is the reemergence of traumatic memories in elderly holocaust survivors and veterans faced with fatal disease or senility (e.g., Holloway and Ursano, 1984).

CONDITIONABILITY Conditioning theory provides an explanation as to how trauma-related cues might acquire the capacity to generate heightened physiologic responses in individuals with PTSD, but it does not explain why, upon exposure to comparably stressful events (i.e., comparable UCSs), some individuals develop PTSD whereas others do not. It may be that individuals who are prone to develop PTSD acquire CRs more readily or extinguish them more slowly, that is, are more "conditionable."

In a clinical sample of patients with generalized anxiety disorder, Pitman and Orr (1986) previously observed slower extinction of a conditioned SC response to angry facial expression CSs. Recently, Orr et al. (1999) examined conditionability in 33 trauma-exposed individuals, 15 with and 18 without PTSD. They employed a Pavlovian differential paradigm that used simple CSs (colored circles) that bore no conceivable relationship to any trauma-related stimuli, in order to test for *de novo* conditioning, as opposed to previously acquired conditioned responding. The UCS was a "highly annoying" electric pulse (shock) to the fingers. Results indicated that the PTSD subjects acquired the conditioned SC response more strongly and extinguished it less readily. The pattern of SC responses shown by the PTSD group during acquisition—namely, SC responses that became increasingly larger across CS+ acquisition trials—was strikingly different from that of the non-PTSD group. This finding is consistent with the proposition that fearfulness increased for the PTSD group as the CS+ acquired signal value for predicting the UCS, whereas for individuals without PTSD, fearfulness decreased as the UCS became more predictable. The PTSD group also showed elevated resting HR and SC levels, larger SC responses during the pre-conditioning habituation phase, a larger unconditioned HR response, and larger HR and corrugator EMG responses during the acquisition phase. These latter find-

ings are consistent with greater anterior paralimbic and limbic (i.e., amygdala) activation during the conditionability experiment.

An important moderator of conditionability appears to be "emotionality," which has been variously conceptualized in terms of anxiety, neuroticism, electrodermal lability, and slower habituation. Individuals identified as more emotional typically have been found to condition more strongly, as indicated by more rapid acquisition and/or greater resistance to extinction of a CR (Boucsein, 1992; Eysenck, 1980; Öhman and Bohlin, 1973; Pitman and Orr, 1986). Eysenck's conditioning model of neurosis highlights the importance of neuroticism and extraversion. An individual who scores high on neuroticism and low on extraversion "is predisposed to neurosis because he reacts strongly to emotionally arousing stimuli and strongly conditions these stimuli" (Eysenck, 1980, p. 163). Neuroticism has been found to predict the development of PTSD following traumatic events (Breslau and Davis, 1992; McFarlane, 1988). Gray (1972) has suggested that the neurologic basis of extraversion-introversion includes the orbitofrontal cortex. As noted previously, PET studies of trauma-related imagery have found increased orbitofrontal (i.e., anterior paralimbic) activation in individuals with PTSD.

Pretrauma individual differences in conditionability could have either a genetic or an acquired basis. Brush (1985) noted that different genetic strains of rats show marked variations in their "emotionality," and that animals identified as having higher emotionality acquired a conditioned response more readily, that is, at lower UCS intensities (see also Owen et al., 1997). A meta-analysis of human twin studies conducted between 1967 and 1985 noted that both emotionality and anxiety have strong genetic influence (McCartney, Harris, and Bernieri, 1990). Results of a twin study of Vietnam veterans showed that PTSD symptoms have a substantial genetic component (True et al., 1993).

Early developmental experiences are also likely to influence emotionality. Research using animals has shown that maternal deprivation can produce adverse consequences in stress-related endocrinologic systems that persist into later life (Rasmusson and Charney, 1997). Increased responsivity to the α -2-adrenergic antagonist yohimbine has been reported for young adult monkeys exposed to early stress associated with variable foraging requirements on their mothers (Rosenblum et al., 1994). Exposure to earlier stressful life events has also been found to increase vulnerability to PTSD (Breslau and Davis, 1992). Finally, it is possible that increased conditionability could result from, and not precede, the stressful event that caused the PTSD.

Classical conditioning provides a powerful explanatory model for several specific features of PTSD. Yet some symptoms associated with PTSD seem to reflect response dispositions that are not a consequence of the immediate presence of any particular CS. For example, PTSD is characterized by self-reported hypervigilance, irritability, and exaggerated startle (table 78.1). Such symptoms could represent manifestations of heightened sensitivity to aversive UCSs, especially in threatening contexts. The amygdala could play a central role in the mediation of individual differences in either pretrauma sensitivity or posttrauma sensitization. Projections from the amygdala influence sympathetic nervous system activity, neuroendocrine responses, startle potentiation, defensive responses, and increased vigilance during fear (Davis, 1997). Each of these has been implicated in one way or another in PTSD.

The diagnostic criteria of DSM-IV for PTSD require that symptoms indicative of hyperarousal not have been present prior to the trauma. However, to the best of our knowledge, no explicit testing has ever been done in this area. Instead, the pretrauma presence of such symptoms could represent dispositions reflecting a heightened sensitivity to noxious stimuli and threatening situations. Individuals with such preexisting dispositions might be more vulnerable to developing PTSD after stressful events. Alternatively, such increased sensitization might result from exposure to the traumatic event. There is ample evidence from the animal literature demonstrating that exposure to a single, severe stressor can cause a range of structural and neurochemical changes consistent with sensitization (Yehuda and Antelman, 1993).

INCREASED SENSITIVITY TO THREAT Individuals with PTSD appear to be more sensitive to threatening stimuli and contexts. Orr, Meyerhoff, et al. (1998) found no differences between PTSD and non-PTSD veterans' resting HR levels or responses to orthostatic, mental arithmetic, or cold pressor challenges, when these were assessed in the veterans' homes. In contrast, higher resting HR, SC, and BP levels frequently have been observed in contexts where PTSD subjects were anticipating exposure to trauma-related cues (reviews in Keane et al., 1998; Orr, 1994). Higher HR and BP levels also have been found in PTSD veterans seeking psychiatric help in a hospital emergency room (ER; Gerardi et al., 1994).

In the conditionability study described earlier (Orr et al., 1999), PTSD subjects showed higher resting SC and HR levels, indicative of heightened sympathetic arousal, before any UCSs were presented. This higher arousal

may have resulted from the PTSD group's greater sensitivity to a context made threatening by anticipation of the electric shock. In turn, this heightened arousal may have played a role in the PTSD subjects' greater conditionability. In fact, higher resting SC levels were found to be correlated with larger differential SC responses to CS+ versus CS- trials during acquisition across subjects. In a study of potentiated startle, Morgan and colleagues (1995) attributed larger fear-potentiated eye-blink startle responses observed in veterans with combat-related PTSD to heightened emotional arousal caused by the threat of shock. Research using animals has shown that amygdala kindling serves to increase fear-potentiated but not baseline startle (Rosen et al., 1996).

DEFENSIVE AUTONOMIC RESPONDING When individuals with PTSD are exposed to sudden, intense acoustic stimuli, they produce larger HR responses. This finding has held in Israeli civilian trauma victims (Shalev et al., 1992), Vietnam veterans (Orr et al., 1995; Paige et al., 1990), Israeli war veterans (Orr, Solomon, et al., 1997), and childhood sexual abuse victims (Metzger et al., 1999), all studied under similar laboratory conditions with the same loud-tone technique (figure 78.3). Even tones of moderate intensity and slower rise time have been found to produce larger HR responses in PTSD subjects (Orr, Lasko, et al., 1997). Increased eye-blink EMG and SC responses, and a slower rate of decline of the latter have also been observed in persons with PTSD (review in Metzger et al., 1999).

An interpretation of increased autonomic responses to tones is that they represent defensive responses that

FIGURE 78.3 Heart rate responses (in square root beats per minute) to sudden 95-dB tones of subjects with (black bars) and without (white bars) posttraumatic stress disorder recruited from various trauma-exposed populations. P = 1, male and female Israeli civilian trauma victims (Shalev et al., 1992); P = 2, male Vietnam combat veterans (Orr et al., 1995); P = 3, male Israeli combat veterans (Orr, Solomon, et al., 1997); P = 4, male and female Israeli civilian trauma victims (Shalev et al., 1997); P = 5, female victims of childhood sexual abuse. (Metzger et al., 1999.)

serve to increase the organism's preparation for motor activity (Graham, 1979), as opposed to orienting responses, which are manifest in HR slowing. Hypervigilance, DSM-IV PTSD symptom D.4, reflects a defensive readiness to respond to threatening stimuli or situations. Observations in animals indicate that amygdala neurons are preferentially activated by high-intensity acoustic stimuli (Bordi and LeDoux, 1992).

Shalev and colleagues (1999) studied patients who presented to an ER following an acute psychologically stressful event. Those who went on to develop chronic PTSD did not show elevated HR responses to sudden, loud tones one week posttrauma, but they did one and four months posttrauma. This finding supports the proposition that defensive responding in PTSD is a consequence of the traumatic event, and that it requires some time to develop (or incubate) after the event's occurrence. In other words, the finding supports the evolution of posttrauma sensitization, as opposed to preexisting sensitivity in PTSD, at least with regard to HR responses to loud tones. Elevated HR responses to loud tones did not arise in patients who developed depression without PTSD, supporting the specificity of this laboratory sign for PTSD.

Paige and colleagues (1990) have provided data supporting defensive cortical responses in PTSD. When exposed to tones of increasing intensity, the P200 event-related potentials (ERPs) of individuals with PTSD showed a decrease in amplitude (i.e., reduction) at higher intensity levels, whereas non-PTSD veterans showed an opposite pattern (i.e., augmentation). Paige and colleagues suggested that the decreased P200 response at higher stimulus intensities resulted from greater nervous system sensitivity with a compensatory cortical reduction of stimulation. The finding has been replicated and extended by Lewine and colleagues (1997) using magnetoencephalography. This technique identified the source of the P200 reduction as reduced activation of the auditory association cortex in PTSD subjects. A normally augmenting N100 response in the PTSD group, found by both Lewine and colleagues and Paige and colleagues, indicated that primary auditory cortex was increasingly activated as stimulus intensity increased. This suggests that some type of sensory gating prevented information associated with high stimulus intensities from reaching association cortex in PTSD subjects.

RESPONSE TO YOHIMBINE CHALLENGE Individuals with PTSD have been found to show greater anxiety, panic attacks, and startle following infusion of yohimbine (which serves to stimulate noradrenaline activity). In response to yohimbine challenge, PTSD patients with panic

attacks showed greater increases in HR, systolic BP, and the plasma noradrenergic metabolite 3-methoxy-4-hydroxy-phenylglycol (MHPG) (Southwick et al., 1993). Bremner, Innis, and colleagues (1997) used [^{18}F]fluorodeoxyglucose to measure brain metabolism following yohimbine administration in 10 PTSD Vietnam combat veterans and 10 healthy noncombat control subjects. Compared to controls, PTSD patients showed decreased metabolism in prefrontal, temporal, parietal, and orbitofrontal cortical areas. These findings support the proposition that the central noradrenergic system is more sensitive in individuals with PTSD.

HYPOTHALAMIC-PITUITARY-ADRENAL (HPA) SENSITIZATION Selye's general adaptation syndrome model predicts that cortisol should be elevated in human stress disorders, but the evidence in PTSD has generally suggested the opposite (Yehuda, Giller, et al., 1991). In contrast, lymphocyte glucocorticoid receptors (GRs) have been found to be increased in number and sensitivity in PTSD subjects (Yehuda, Lowy, et al., 1991). The finding of a larger number of GRs is consistent with observations of low cortisol in PTSD, in that low circulating levels of a hormone or neurotransmitter are typically associated with compensatory receptor up-regulation. Alternatively, GRs may exert a primary influence on cortisol level by mediating the strength of negative feedback (Yehuda, Boissoneau, et al., 1995). This is supported by the observation that cortisol following a low dose of dexamethasone is suppressed to a greater extent in patients with PTSD (Yehuda et al., 1993), the opposite of the classic nonsuppression of cortisol found in major depression. Nonsuppression of cortisol results from reduced negative feedback inhibition of dexamethasone on the release of CRH and ACTH. Stronger cortisol suppression suggests more effective negative feedback inhibition, also referred to as a sensitized HPA axis (Yehuda, 1997). Resnick and colleagues (1995) found that women who had experienced prior sexual victimization showed smaller cortisol responses to a subsequent rape incident, suggesting that previous trauma may have sensitized their HPA axes. Under certain conditions, experimental stress may induce a sensitized HPA axis in rats (Liberzon, Krstov, and Young, 1997).

PTSD, hormones, and memory

A substantial body of animal research has demonstrated that stress hormones, especially epinephrine but also glucocorticoids, ACTH, vasopressin, and CRH, can strengthen emotional memory or conditioned responses (De Wied, 1969; Gold and Van Buskirk, 1975; Roozendaal

TABLE 78.2
Probability of PTSD as a function of heart rate immediately after an acute traumatic event
(Shalev, Sahar, et al., 1998)

Heart Rate	PTSD Patients	non-PTSD Patients	Total	PTSD Percent
All	20	67	87	23
>70	20	63	83	24
>80	19	47	66	29
>90	15	16	31	48
>100	7	9	16	44
>110	5	1	6	83

and McGaugh, 1996). This effect has been found to require an intact amygdala in both animals and humans and is eliminated by β -adrenergic blockade with propranolol, given either systemically or injected into the amygdala (review in Cahill and McGaugh, 1998). Corticosteroids potentiate conditioned fear (Corodimas et al., 1994). Propranolol antagonizes the enhanced conditioned fear produced by CRH (Cole and Koob, 1988).

Based upon the above animal research, Pitman (1989) theorized that stress hormones and neuromodulators released in response to a traumatic event may overconsolidate memories of the event. These memories subsequently may manifest themselves as intrusive recollections and reexperiencing symptoms. Recalling the event may release additional stress hormones that further enhance the strength of the traumatic memory, creating a positive feedback loop that may eventuate in PTSD. An implication of this theory is that pharmacologic intervention—for example, administration of a β -blocker such as propranolol—soon after a traumatic event might block this cycle of events and prevent the development of PTSD.

NEUROPEPTIDE INFLUENCES ON TRAUMATIC MEMORY RETRIEVAL Once PTSD has developed, it is too late to study traumatic memory consolidation. However, animal research has shown that hormonal effects on memory are biphasic, that is, exerted at the time of consolidation and again at the time of retrieval. Memory consolidation and retrieval are influenced by various hormonal interventions in parallel ways (Kovacs and Telegdy, 1982). In animals, the posterior pituitary neuropeptide vasopressin has been found to facilitate the acquisition and resistance to extinction of conditioned avoidance responses, whereas oxytocin (which exerts effects opposite to vasopressin) suppresses acquisition and enhances extinction (van Wimersma Greidanus, Jolles, and De Wied, 1985). The effects of vasopressin and oxytocin on physiologic responses during personal combat imagery were examined in 43 Vietnam veterans with PTSD (Pitman, Orr, and Lasko, 1993). Veterans were

randomly assigned to receive either double-blind, intranasal vasopressin, placebo, or oxytocin prior to the experiment. Mean physiologic responses during personal combat imagery were in the predicted direction, namely, vasopressin > placebo > oxytocin (figure 78.4). These results are consistent with enhancing and inhibiting effects exerted by vasopressin and oxytocin (respectively) on memory retrieval, and they support a role for hormonal modulation of memory in PTSD.

POSTTRAUMA HYPERADRENERGIC STATE In patients presenting to a hospital ER following a psychologically stressful event, Shalev, Sahar, and colleagues (1998) found higher initial HRs in those who went on to develop PTSD but not depression without PTSD (Shalev, Freedman, et al., 1998) four months later. The PTSD effect persisted even when ER HRs were adjusted for differences in the severity of the psychological trauma

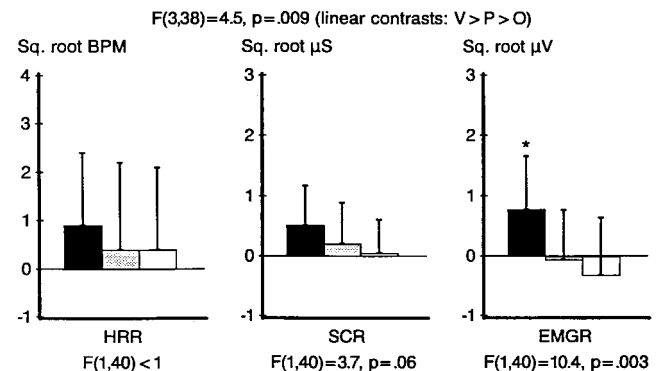

FIGURE 78.4 Mean physiologic responses of 43 Vietnam combat veterans with posttraumatic stress disorder during personal combat imagery one hour following intranasal study medication: V, vasopressin (black bars, $n = 13$); P = placebo (gray bars, $n = 15$); O, oxytocin (white bars, $n = 15$); HRR, heart rate response; SCR, skin conductance response; EMGR, left lateral frontalis electromyogram response; BPM, beats per minute; μS , microsiemens; μV , microvolts. Lines above bars indicate standard deviations. Star indicates response significantly different from placebo at $p = .02$. (Pitman, Orr, and Lasko, 1993; reprinted from *Psychiatry Research*, vol. 48, no. 2, August 1993, p. 113; in the public domain.)

or the subjective response. Table 78.2 presents the probability of PTSD, which rose rapidly as a function of ER HR. Not shown in this table is that 13 (72%) of the 18 patients with ER HRs ≤ 90 beats per minute (BPM) who had PTSD at one month remitted over the next three months. In sharp contrast, none (0%) of the 15 patients with ER HRs >90 BPM who had PTSD at one month showed remission at four months. A plausible explanation for this finding is that the patients who had higher HRs in the ER had released more circulating epinephrine in response to the traumatic event, and that this served to overconsolidate memories of it, leading to PTSD.

Memory and hippocampal structure in PTSD

The overly strong conditioned responses found in PTSD might be regarded as one form of so-called implicit memory, in that they do not necessarily require conscious recollection for their expression. In contrast to the overly strong emotional memories for traumatic events found in this disorder is a relative weakness of memory for nonemotional information. A number of studies have reported deficits in declarative memory for material unrelated to PTSD subjects' traumatic events (Bremner et al., 1995b; Bremner et al., 1993; Jenkins et al., 1998; Yehuda, Keefe, et al., 1995).

REDUCED HIPPOCAMPAL VOLUME Declarative, or explicit, memory is widely accepted to be mediated by the medial temporal lobe, especially the hippocampus. Animal research has indicated that this brain structure may be damaged by stress (Uno et al., 1989), an effect attributed to cortisol (Sapolsky et al., 1990). These findings motivated four recent studies of hippocampal volume, two in Vietnam combat veterans (Bremner et al., 1995a; Gurvits et al., 1996) and two in childhood physical and sexual abuse subjects (Bremner, Randall, et al., 1997; Stein et al., 1997). Each of these studies found significantly smaller hippocampal volumes in PTSD subjects than in non-PTSD subjects (examples in figure 78.5). A fifth study (Schuff et al., 1997), which combined MRI and magnetic resonance spectroscopy, noted 6% smaller right hippocampal volumes in veterans with combat-related PTSD. Although the group difference was not significant in the small sample sizes studied, the effect size was substantial (.71). Moreover, results of the spectroscopic imaging revealed less of the amino acid N-acetyl aspartate (NAA) in the PTSD group's right hippocampus, suggesting lower neuronal density in this structure.

The preceding findings raise the possibility that traumatic stress damages the human hippocampus (Sapolsky, 1996). In support, Gurvits and colleagues (1996)

found a strong negative correlation between severity of past combat exposure in Vietnam and hippocampal volume (figure 78.6). However, the absence of hypercortisolism in PTSD described earlier creates a formidable problem for this interpretation. Alternative explanations include the possibility that diminished hippocampal volume represents a risk factor for exposure to stressful events and/or a vulnerability factor for the development of PTSD upon such exposure. It is also possible that alcohol or other substance abuse associated with PTSD exerts a toxic effect, although most studies have attempted to control for this factor.

FUNCTIONAL NEUROIMAGING OF HIPPOCAMPUS

Functional neuroimaging studies of the hippocampus in PTSD have lagged far behind structural studies and represent a needed area of investigation. Semple and colleagues (1993) measured rCBF in six PTSD combat veterans with recent substance abuse or dependence and seven normal (noncombat) controls at rest and during auditory continuous performance and word-generation tasks. PTSD subjects showed trends for increased rCBF in orbitofrontal cortex and decreased left/right hippocampal ratios across conditions. However, confounding of PTSD diagnosis with recent substance use, together with the absence of a trauma-exposed control group, cause the results of this study to be of uncertain significance. In their [^{18}F]fluorodeoxyglucose PET study described previously, Bremner, Innis, and colleagues (1997) found that yohimbine challenge, which activates noradrenergic activity in the locus coeruleus, produced a significant reduction in rCBF in the hippocampus in Vietnam combat veterans with PTSD.

NON-MEMORY FUNCTIONS OF HIPPOCAMPUS In addition to its well-recognized role in the formation of declarative memory, the hippocampus plays a role in regulating behavior. Douglas (1972) described the hippocampus as "the organ of expression of internal inhibition," citing deficiencies of hippocampectomized animals in habituation, extinction, reversal learning, and other behaviors in which Pavlovian internal inhibition plays a prominent role (see also Kimble, 1968). In contrast, Douglas attributed Pavlovian excitation to the amygdala. In a similar vein, Devenport, Devenport, and Holloway (1981) found that the hippocampus functions to increase the animal's behavioral variability and resistance to stereotypy, noting that counterproductive habits are not readily discarded by hippocampal-lesioned rats. As noted in the psychophysiologic studies described earlier, PTSD subjects suffer from impaired habituation and extinction on either a preexisting or

MR Image From Non-PTSD Veteran

MR Image From PTSD Veteran

FIGURE 78.5 Magnetic resonance images illustrating smaller left and right hippocampi in a Vietnam combat veteran with PTSD (bottom) than in one without PTSD (top). (Gurvits et al.,

1996; reprinted from *Biological Psychiatry*, vol. 40, no. 11, December 1, 1996, p. 1096; in the public domain.)

acquired basis. Reduced hippocampal function could offer an anatomic explanation for these phenomena in PTSD patients. As discussed previously, another candidate brain area for internal inhibition is anterior cingulate cortex.

Conclusions

“HOT” AND “COOL” MEMORY SYSTEMS IN PTSD
In an overview of more than a decade of research by various authors, Metcalfe and Jacobs (1996) have dis-

FIGURE 78.6 Total hippocampal volume as a function of Combat Exposure Scale score. Closed circles, PTSD subjects; open circles, non-PTSD subjects. (Gurvits et al., 1996; reprinted from *Biological Psychiatry*, vol. 40 no. 11, December 1, 1996, p. 1096; in the public domain.)

tinguished between an amygdala-centered (anterior paralimbic) emotional, “hot,” memory system, and a hippocampus-centered (posterior paralimbic) cognitive, “cool” memory system. This distinction has received support from case studies of humans with selective amygdala and/or hippocampal damage (Bechara et al., 1995). Metcalfe and Jacobs theorized that the “hot” amygdala system is critically involved in traumatic memory formation and the pathogenesis of PTSD. The “cool” hippocampal system either is not active in traumatic memory formation, or it may even be deactivated under stress. As we have noted, the specific symptoms of PTSD may be fruitfully conceptualized as the products of fear conditioning. The critical role of the amygdala in this process has been amply demonstrated in preclinical research. Results of PTSD neuroimaging studies point to anterior paralimbic activation during traumatic reexperiencing. Indirect evidence suggests that hormonal potentiation of memory consolidation in the amygdala is involved in the pathogenesis of PTSD. Not all psychobiologic aspects of PTSD, however, can be subsumed under a conditioning model. Sensitization appears to represent a necessary additional dimension.

Findings of impaired declarative memory and diminished hippocampal volume in PTSD subjects lend support to the other half of Metcalfe and Jacobs’ theory. A deficit in inhibitory functions due to functional posterior paralimbic (i.e., hippocampal) impairment, either on a preexisting or acquired basis, could have a permissive

influence on the overdevelopment of anterior paralimbic excitation in the pathogenesis of PTSD.

GAPS AND CONTRADICTIONS Some patients with PTSD have detailed recollections that suggest enhanced, rather than impaired, declarative memory at the time of the traumatic event, which would imply heightened acute hippocampal function. Cahill and McGaugh (1998) have argued that the amygdala serves to activate various cortical brain areas, including the hippocampus. The implication is that the amygdala and the hippocampus may work in concert in the pathogenesis of PTSD.

The paradoxical finding of lower cortisol levels in PTSD is difficult to reconcile with the proposition that diminished hippocampal volume in this disorder represents a stress- or cortisol-induced phenomenon. It is tempting to speculate that cortisol levels immediately following the traumatic event are initially high in PTSD and then become lower in some compensatory manner. This result would be consistent with results from animal research indicating that corticosteroids potentiate conditioned fear and memory consolidation. However, the empirical PTSD data do not seem to be consistent with this proposition; if anything, immediate posttrauma cortisol levels appear to be lower in persons who go on to develop PTSD (McFarlane, Atchison, and Yehuda, 1997). A potential explanation of this contradiction is that increased GR sensitivity represents a pretrauma vulnerability factor for PTSD, either constitutional or acquired from prior stressful experience (Yehuda, 1997). According to this theory, cortisol stimulated at the time of the traumatic event would exert a greater initial physiologic impact at more sensitive brain GR sites before it was turned off by a supersensitive HPA negative feedback axis. Although tempting, this explanation is speculative and in need of supporting data.

Ultimately, the resolution of these and other questions will require prospective investigations, in which subjects are studied before and after the occurrence of a psychologically stressful event. Such studies will no doubt be difficult and expensive but have become essential to the advancement of the field.

Whatever data future research may yield, it is clear that the interchange between basic cognitive neuroscience and clinical investigation of PTSD will continue to yield exciting insights for both fields.

79 The Neuroscience of Affective Style

RICHARD J. DAVIDSON

ABSTRACT Among the most striking features of human emotion is the pronounced variability across individuals in the quality and intensity of emotional reactions to the same elicitor. This chapter introduces a framework for the objective neuroscientific study of such individual differences in affective style. The constituents of affective style are first reviewed and methods for their objective study described. The circuitry underlying two major forms of emotion and motivation is then presented. The foundations of this analysis are derived from the animal literature, and such observations are complemented by recent human neuroimaging studies. Emphasis is placed on the prefrontal cortex, the amygdala, and the ventral striatum in the generation of certain forms of positive and negative affect. Next, individual differences in aspects of this circuitry are considered. Here the emphasis is on individual differences in activation asymmetry in regions of the prefrontal cortex that appear to play a fundamental role in approach and withdrawal motivational disposition. Data are reviewed that indicate that individual differences in baseline measures of prefrontal activation are stable over time and predict both psychological and biological measures that have been linked to affective style. Finally, the implications of these data for conceptualizing the affective dysfunction in certain forms of psychopathology are considered.

Among the most striking features of human emotion is the variability that is apparent across individuals in the quality and intensity of emotional reactions to similar incentives and challenges and in the intensity and valence of dispositional mood. The broad range of differences in these varied affective phenomena has been referred to as *affective style* (Davidson, 1992). Differences among people in affective style appear to be associated with temperament (Kagan, Reznick, and Snidman, 1988), personality (Gross, Sutton, and Ketelaar, 1998), health (Ryff and Singer, 1998), and vulnerability to psychopathology (Meehl, 1975). Moreover, such differences are not a unique human attribute but appear to be present in a number of different species (e.g., Davidson, Kalin, and Shelton, 1993; Kalin, 1993).

In the next section of this chapter, conceptual distinctions among the various components of affective style will be introduced and methodological challenges to their study will be highlighted. The third section will present a brief overview of the anatomy of two basic motivational/emotional systems—the approach and

withdrawal systems—and will review research using neuroimaging methods to make inferences about the circuitry associated with these affective dispositions. The fourth section will consider individual differences in these basic systems and indicate how such differences might be studied. The final section will consider some of the implications of the research on affective style for conceptualizing the dysfunctions in emotion regulation in psychopathology, particularly mood and anxiety disorders.

The constituents of affective style

Many phenomena are subsumed under the rubric of affective style. A concept featured in many discussions of affective development, affective disorders, and personality is *emotion regulation* (Thompson, 1994). Emotion regulation refers to a broad constellation of processes that serve to either amplify, attenuate, or maintain the strength of emotional reactions. Included among these processes are certain features of attention that regulate the extent to which an organism can be distracted from a potentially aversive stimulus (Derryberry and Reed, 1996) and the capacity for self-generated imagery to replace emotions that are unwanted with more desirable imagery scripts. Emotion regulation can be both automatic and controlled. Automatic emotion regulation may result from the progressive automatization of processes that initially were voluntary and controlled and have evolved to become more automatic with practice. We hold the view that regulatory processes are an intrinsic part of emotional behavior, and rarely does an emotion get generated in the absence of recruiting associated regulatory processes. For this reason, it is often conceptually difficult to distinguish sharply between where an emotion ends and where regulation begins. Even more problematic is the methodological challenge of operationalizing these different components in the stream of affective behavior.

When considering the question of individual differences in affective behavior, one must specify the particular response systems in which the individual differences are being explored. It is not necessarily the case that the same pattern of individual differences would be found across response systems. Thus, for example, an individual

may have a low threshold for the elicitation of the subjective experience (as reflected in self-reports) of a particular emotion but a relatively high threshold for the elicitation of a particular physiological change. It is important not to assume that individual differences in any parameter of affective responding will necessarily generalize across response systems, within the same emotion. Equally important is the question of whether individual differences associated with the generation of a particular specific emotion will necessarily generalize to other emotions. For example, are those individuals who are behaviorally expressive in response to a fear challenge also likely to show comparably high levels of expressivity in response to positive incentives? While systematic research on this question is still required, initial evidence suggests that at least certain aspects of affective style may be emotion specific, or at least valence specific (e.g., Wheeler, Davidson, and Tomarken, 1993).

In addition to emotion regulation, there are also likely to be intrinsic differences in certain components of emotional responding. There are likely to be individual differences in the *threshold* for eliciting components of an emotion, given a stimulus of a particular intensity. Thus some individuals are likely to produce facial signs of disgust upon presentation of a particular intensity of noxious stimulus, whereas other individuals may require a more intense stimulus for the elicitation of the same response at a comparable intensity. This suggestion implies that dose-response functions may reliably differ across individuals. Unfortunately, systematic studies of this kind have not been performed, in part because of the difficulty of creating stimuli that are graded in intensity and designed to elicit the same emotion. In the olfactory and gustatory modalities, there are possibilities of creating stimuli that differ systematically in the concentration of a disgust-producing component and then obtaining psychophysical threshold functions that would reveal such individual differences. However, the production of such intensity-graded stimuli in other modalities will likely be more complicated, though with the development of large, normatively rated complex stimulus sets, this may be possible. An example is the *International Affective Picture System* (Lang, Bradley, and Cuthbert, 1995) developed by Peter Lang and his colleagues. This set includes a large number of visual stimuli that have been rated on valence and arousal dimensions and that comprise locations throughout this two-dimensional space. The density of stimulus exemplars at all levels within this space allows for the possibility of selecting stimuli that are graded in intensity for dose-response studies of the sort described.

There are also likely to be individual differences in the *peak* or *amplitude* of the response. Upon presentation

of a series of graded stimuli that differ in intensity, the maximum amplitude in a certain system (e.g., intensity of a facial contraction, change in heart rate, etc.) is likely to differ systematically across subjects. Some individuals will respond with a larger amplitude peak than will others. Again, such individual differences may well be quite specific to particular systems and will not necessarily generalize across systems, even within the same emotion. Thus the individual who is in the tail of the distribution in her heart-rate response to a fearful stimulus will not necessarily be in the tail of the distribution in her facial response.

Another parameter that is likely to differ systematically across individuals is the *rise time to peak*. Some individuals will rise quickly in a certain response system, whereas others will rise more slowly. There may be an association between the peak of the response and the rise time to the peak within certain systems for particular emotions. Thus it may be the case that for anger-related emotion, those individuals with higher peak vocal responses also show a faster rise time, but to the best of my knowledge, there are no systematic data related to such differences.

Finally, another component of intrinsic differences across individuals is the *recovery time*. Following perturbation in a particular system, some individuals recover quickly, and others recover slowly. For example, following a fear-provoking encounter, some individuals show a persisting heart-rate elevation that might last for minutes, whereas other individuals show a comparable peak and rise time but recover much more quickly. Of course, as with other parameters, there are likely to be differences in recovery time across different response systems. Some individuals may recover rapidly in their expressive behavior, while recovering slowly in certain autonomic channels. The potential significance of such dissociations has not been systematically examined.

The specific parameters of individual differences that are delineated in the preceding paragraphs describe *affective chronometry*—the temporal dynamics of affective responding. Very little is known about the factors that govern these individual differences and the extent to which such differences are specific to particular emotion response systems or generalize across emotions. (For example, is the heart-rate recovery following fear similar to that following disgust?) Moreover, the general issue of the extent to which these different parameters that have been identified are orthogonal or correlated features of emotional responding is an empirical question that has yet to be answered. For reasons that I hope to make clear, affective chronometry is a particularly important feature of affective style and is likely to play a key role in determining vulnerability to psychopathology. It is also

a feature of affective style that is methodologically tractable and can yield to experimental study of its neural substrates.

We also hold that affective style is critical in understanding the continuity between normal and abnormal functioning and in the prediction of psychopathology and the delineation of vulnerability. On the opposite side of the spectrum, such individual differences in affective style will also feature centrally in any comprehensive theory of resilience. The fact that some individuals reside “off the diagonal” and appear to maintain very high levels of psychological well-being despite their exposure to objective life adversity is likely related to their affective style (Ryff and Singer, 1998). Some of these implications will be discussed at the end of this chapter.

We first consider some of the neural substrates of two fundamental emotion systems. This discussion provides the foundation for a consideration of individual differences in these systems and the neural circuitry responsible for such differences.

The anatomy of approach and withdrawal

Although the focus of my empirical research has been on measures of prefrontal brain activity, it must be emphasized at the outset that the circuit instantiating emotion in the human brain is complex and involves a number of interrelated structures. Precious few empirical studies using modern neuroimaging procedures that afford a high degree of spatial resolution have yet been performed (see George et al., 1995; Paradiso et al., 1997, for examples). Therefore, hypotheses about the set of structures that participate in the production of emotion must necessarily be speculative and based to a large extent on the information available from the animal literature (e.g., LeDoux, 1987, 1996) and from theoretical accounts of the processes involved in human emotion.

Based upon the available strands of theory and evidence, numerous scientists have proposed two basic circuits each mediating different forms of motivation and emotion (see, e.g., Gray, 1994; Lang, Bradley, and Cuthbert, 1990; Davidson, 1995). The approach system facilitates appetitive behavior and generates certain types of positive affect that are approach related—for example, enthusiasm, pride, and so on (see Depue and Collins, in press, for review). This form of positive affect is usually generated in the context of moving toward a desired goal (see Lazarus, 1991; Stein and Trabasso, 1992, for theoretical accounts of emotion that place a premium on goal states). The representation of a goal state in working memory is hypothesized to be implemented in dorsolateral prefrontal cortex. The medial prefrontal cortex

seems to play an important role in maintaining representations of behavioral-reinforcement contingencies in working memory (Thorpe, Rolls, and Maddison, 1983). In addition, output from the medial prefrontal cortex to nucleus accumbens (NA) neurons modulates the transfer of motivationally relevant information through the NA (Kalivas, Churchill, and Klitenick, 1993). The basal ganglia are hypothesized to be involved in the expression of the abstract goal in action plans and in the anticipation of reward (Schultz, Apicella, et al., 1995; Schultz, Romo, et al., 1995). The NA, particularly the caudomedial shell region of the NA, is a major convergence zone for motivationally relevant information from a myriad of limbic structures. Cells in this region of the NA increase their firing rate during reward expectation (see Schultz, Apicella, et al., 1995). There are likely other structures involved in this circuit that depend on a number of factors including the nature of the stimuli signaling appetitive information, the extent to which the behavioral-reinforcement contingency is novel or overlearned, and the nature of the anticipated behavioral response.

It should be noted that the activation of this approach system is hypothesized to be associated with one particular form of positive affect and not all forms of such emotion. It is specifically predicted to be associated with *pre-goal-attainment positive affect*, the form of positive affect that is elicited as an organism moves closer to an appetitive goal. *Post-goal-attainment positive affect* represents another form of positive emotion that is not expected to be associated with activation of this circuit (see Davidson, 1994, for a more extended discussion of this distinction). This latter type of positive affect may be phenomenologically experienced as contentment and is expected to occur when the prefrontal cortex goes offline after a desired goal has been achieved. Cells in the NA have also been shown to decrease their firing rate during post-goal-consummatory behavior (e.g., Henriksen and Giacchino, 1993).

Lawful individual differences can enter into many different stages of the approach system. Such individual differences will be considered in detail later. For the moment, it is important to underscore two issues. One is that there are individual differences in the tonic level of activation of the approach system that alters an individual's propensity to experience approach-related positive affect. Second, there are likely to be individual differences in the capacity to shift between pre- and post-goal attainment positive affect and in the ratio between these two forms of positive affect. Upon reaching a desired goal, some individuals will immediately replace the just-achieved goal with a new desired goal, and so will have little opportunity to experience post-goal-attainment positive affect, or contentment. There may be an

optimal balance between these two forms of positive affect, though this issue has never been studied.

There appears to be a second system concerned with the neural implementation of withdrawal. This system facilitates the withdrawal of an individual from sources of aversive stimulation and generates certain forms of negative affect that are withdrawal related. Both fear and disgust are associated with increasing the distance between the organism and a source of aversive stimulation. From invasive animal studies and human neuroimaging studies, it appears that the amygdala is critically involved in this system (e.g., LeDoux, 1987, 1996). Using functional magnetic resonance imaging (fMRI) we have recently demonstrated for the first time activation in the human amygdala in response to aversive pictures compared with neutral control pictures (Irwin et al., 1996). Several experiments using both fMRI and the lesion method have further supported the idea that the amygdala is a key structure in the perception of facial expressions of fear (e.g., Adolphs et al., 1995; Breiter et al., 1996; Morris et al., 1996). Interestingly, recent evidence indicates that the perception of facial signs of disgust is associated with activation of the anterior insular cortex but not the amygdala (e.g., Phillips et al., 1997). These data imply that certain components of the circuit underlying the withdrawal emotions of fear and disgust may be the same, but other components appear to differ. The pronounced vagal response often associated with disgust may in part be responsible for the insular activation (see Cacioppo et al., 1993), though this conjecture has never been formally tested. The temporal polar region also appears to be activated during withdrawal-related emotion (e.g., Reiman et al., 1989; but see Drevets et al., 1992). Some evidence suggests that at least in humans, these effects appear to be more pronounced on the right side of the brain (see Davidson, 1992, 1993, for reviews). In the human electrophysiological studies, the right frontal region is also activated during withdrawal-related negative affective states including both fear and disgust (e.g., Davidson, Ekman, et al., 1990). At present it is not entirely clear whether this EEG change reflects activation at a frontal site or whether the activity recorded from the frontal scalp region is volume-conducted from other cortical loci. The resolution of this uncertainty must await additional studies using positron emission tomography (PET) or fMRI, which have sufficient spatial resolution to differentiate among different anterior cortical regions. In addition to the temporal polar region, the amygdala, and possibly the prefrontal cortex, it is also likely that the basal ganglia and hypothalamus are involved in the motor and autonomic components, respectively, of withdrawal-related negative affect (see Smith, DeVita, and Astley, 1990). In sum-

mary, from the evidence currently available, the right-sided anterior cortical activation appears to be common to both fear and disgust; activation of the amygdala appears to be more specific to fear; and activation of the insular cortex appears to be more specific to disgust. These findings are thus consistent with both discrete and dimensional views of emotion, suggesting that some circuitry may be unique to specific discrete emotions and other circuitry may code for broader dimensional characteristics.

The nature of the relation between these two hypothesized affect systems also remains to be delineated. The emotion literature is replete with different proposals regarding the interrelations among different forms of positive and negative affect. Some theorists have proposed a single bivalent dimension that ranges from unpleasant to pleasant affect, with a second dimension that reflects arousal (e.g., Russell, 1980). Other theorists have suggested that affect space is best described by two orthogonal positive and negative dimensions (e.g., Watson and Tellegen, 1985). Still other workers have suggested that the degree of orthogonality between positive and negative affect depends upon the temporal frame of analysis (Diener and Emmons, 1984). This formulation holds that when assessed in the moment, positive and negative affect are reciprocally related, but when examined over a longer time frame (e.g., dispositional affect), they are orthogonal. It must be emphasized that these analyses of the relation between positive and negative affect are all based exclusively on measures of self-report, and therefore the generalizability to other measures of affect is uncertain. However, based upon new data that will be described later, we believe that a growing corpus of data does indeed indicate that one function of positive affect is to inhibit concurrent negative affect.

What do individual differences in asymmetric prefrontal activation reflect?

This section will present a brief overview of recent work from my laboratory that was designed to examine individual differences in measures of prefrontal activation and their relation to different aspects of emotion, affective style, and related biological constructs. These findings will be used to address the question of what underlying constituents of affective style such individual differences in prefrontal activation actually reflect.

In both infants (Davidson and Fox, 1989) and adults (Davidson and Tomarken, 1989) there are large individual differences in baseline electrophysiological measures of prefrontal activation, and such individual variation is associated with differences in aspects of affective reactivity. In infants, Davidson and Fox (1989) reported that

10-month-old babies who cried in response to maternal separation were more likely to have less left- and greater right-sided prefrontal activation during a preceding resting baseline compared with those infants who did not cry in response to this challenge. In adults, we first noted that the phasic influence of positive and negative emotion elicitors (e.g., film clips) on measures of prefrontal activation asymmetry appeared to be superimposed on more tonic individual differences in the direction and absolute magnitude of asymmetry (Davidson and Tomarken, 1989).

During our initial explorations of this phenomenon, we needed to determine if baseline electrophysiological measures of prefrontal asymmetry were reliable and stable over time and thus could be used as a traitlike measure. Tomarken and colleagues (1992) recorded baseline brain electrical activity from 90 normal subjects on two occasions separately by approximately three weeks. At each testing session, brain activity was recorded during 8 one-minute trials, four with eyes open and four with eyes closed, presented in counterbalanced order. The data were visually scored to remove artifact and then Fourier-transformed. Our focus was on power in the alpha band (8–13 Hz), though we extracted power in all frequency bands. (See Davidson, Chapman, et al., 1990, for a discussion of power in different frequency bands and their relation to activation.) We computed coefficient alpha as a measure of internal consistency reliability from the data for each session. The coefficient alphas were quite high, with all values exceeding .85, indicating that the electrophysiological measures of asymmetric activation indeed showed excellent internal consistency reliability. The test-retest reliability was adequate with intraclass correlations ranging from .65 to .75 depending on the specific sites and methods of analysis. The major conclusion from this study was the demonstration that measures of activation asymmetry based on power in the alpha band from prefrontal scalp electrodes showed both high internal-consistency reliability and acceptable test-retest reliability to be considered a traitlike index.

On the basis of our prior data and theory, we reasoned that extreme left and extreme right frontally activated subjects would show systematic differences in dispositional positive and negative affect. We administered the trait version of the Positive and Negative Affect Scales (PANAS; Watson, Clark, and Tellegen, 1988) to examine this question and found that the left-frontally activated subjects reported more positive and less negative affect than their right-frontally activated counterparts (Tomarken et al., 1992; see figure 79.1). More recently with Sutton (Sutton and Davidson, 1997) we showed that scores on a self-report measure designed to operationalize Gray's concepts of Behavioral Inhibition

FIGURE 79.1 Dispositional positive affect (from scores on the PANAS–General Positive Affect Scale) in subjects who were classified as extreme and stable left-frontally active ($N = 14$) and extreme and stable right-frontally active ($N = 13$) on the basis of electrophysiological measures of baseline activation asymmetries on two occasions separated by three weeks. (From Tomarken et al., 1992.)

and Behavioral Activation (the BIS/BAS scales; Carver and White, 1994) were even more strongly predicted by electrophysiological measures of prefrontal asymmetry than were scores on the PANAS scales (see figure 79.2). Subjects with greater left-sided prefrontal activation reported more relative BAS to BIS activity than did subjects exhibiting more right-sided prefrontal activation.

We also hypothesized that our measures of prefrontal asymmetry would predict reactivity to experimental elicitors of emotion. The model that we have developed over the past several years (see Davidson, 1992, 1994, 1995, for background) features individual differences in prefrontal activation asymmetry as a reflection of a diathesis which modulates reactivity to emotionally significant events. According to this model, individuals who differ in prefrontal asymmetry should respond differently to an elicitor of positive or negative emotion, even when baseline mood is partialled out. We performed an experiment to examine this question (Wheeler, Davidson, and Tomarken, 1993; see also Tomarken, Davidson, and Henriques, 1990). We presented short film clips designed to elicit positive or negative emotion. Brain electrical activity was recorded prior to the presentation of the film clips. Just after the clips were presented, subjects were asked to rate their emotional experience during the preceding film clip. In addition, subjects completed scales that were designed to reflect their mood at baseline. We found that individual differences in prefrontal asymmetry predicted the emotional response to the films even after measures of baseline mood were statistically removed. Those individuals with more left-sided prefrontal activation at baseline reported more positive affect to the positive film clips, and those with more

FIGURE 79.2 Relations between electrophysiological measures of asymmetry and the difference between the standardized score on the Behavioral Activation and Behavioral Inhibition Scales (BAS/BIS scales; Carver and White, 1994), $N = 46$. Electrophysiological data were recorded from each subject on two separate occasions separated by 6 weeks. The BIS/BAS scales were also administered on these two occasions. Data were averaged across the two time periods prior to performing correlations. The topographic map displays the correlations between alpha power asymmetry (log right minus log left alpha power; higher values denote greater relative left-sided activation) and the difference score between the standardized BAS minus BIS scales. After correlations were per-

formed for each homologous region, a spline-interpolated map was created. The lighter values of the scale denote positive correlations. The figure indicates that the correlation between the BAS-BIS difference score and the electrophysiology asymmetry score is highly positive in prefrontal scalp regions, denoting that subjects with greater relative left-sided activation report more relative Behavioral Activation than Behavioral Inhibition tendencies. The relation between asymmetric activation and the BAS-BIS difference is highly specific to the anterior scalp regions, as the correlation drops off rapidly more posteriorly. The correlation in the prefrontal region is significantly larger than the correlation in the parieto-occipital region. (From Sutton and Davidson, 1997.)

right-sided prefrontal activation reported more negative affect to the negative film clips. These findings support the idea that individual differences in electrophysiological measures of prefrontal activation asymmetry mark some aspect of vulnerability to positive and negative emotion elicitors. The fact that such relations were obtained following the statistical removal of baseline mood indicates that any difference between left and right frontally activated subjects in baseline mood cannot account for the prediction of film-elicited emotion effects that were observed.

In a very recent study, we examined relations between individual differences in prefrontal activation asymmetry and the emotion-modulated startle (Davidson et al., in preparation). In this study, we presented pictures from the *International Affective Picture System* (Lang, Bradley, and Cuthbert, 1995) while acoustic startle probes were presented and the EMG-measured blink

response from the orbicularis oculi muscle region was recorded (see Sutton et al., 1997, for basic methods). Startle probes were presented both during the 6-second slide exposure and 500 ms following the offset of the pictures, on separate trials.¹ We interpreted startle magnitude during picture exposure as providing an index related to the peak of emotional response, while startle magnitude following the *offset* of the pictures was taken to reflect the recovery from emotional challenge. Used in this way, startle probe methods can potentially provide new information on the time course of emotional responding. We expected that individual differences during actual picture presentation would be less pronounced than individual differences following picture presentation, since an acute emotional stimulus is likely to pull for a normative response across subjects, yet individuals are likely to differ dramatically in the time to recover. Similarly, we predicted that individual differences

in prefrontal asymmetry would account for more variance in predicting magnitude of recovery (i.e., startle magnitude poststimulus) than in predicting startle magnitude during the stimulus. Our findings were consistent with our predictions and indicated that subjects with greater right-sided prefrontal activation show a larger blink magnitude following the offset of the negative stimuli, after the variance in blink magnitude *during* the negative stimulus was partialled out. Measures of prefrontal asymmetry did not reliably predict startle magnitude during picture presentation. The findings from this study are consistent with our hypothesis and indicate that individual differences in prefrontal asymmetry are associated with the time course of affective responding, particularly the recovery following emotional challenge.

In addition to the studies using self-report and psychophysiological measures of emotion that have been described, we have also examined relations between individual differences in electrophysiological measures of prefrontal asymmetry and other biological indices that in turn have been related to differential reactivity to stressful events. Two recent examples from our laboratory include measures of immune function and cortisol. In the case of the former, we examined differences between left and right prefrontally activated subjects in natural killer cell activity, since declines in NK activity have been reported in response to stressful, negative events (Kiecolt-Glaser and Glaser, 1991). We predicted that subjects with right prefrontal activation would exhibit lower NK activity compared with their left-activated counterparts because the former type of subject has been found to report more dispositional negative affect, to show higher relative BIS activity, and to respond more intensely to negative emotional stimuli. We found that right-frontally activated subjects indeed had lower levels of NK activity compared with their left frontally activated counterparts (Kang et al., 1991).

In collaboration with Kalin, our laboratory has been studying similar individual differences in scalp-recorded measures of prefrontal activation asymmetry in rhesus monkeys (Davidson, Kalin, and Shelton, 1992, 1993). Recently we acquired measures of brain electrical activity from a large sample of rhesus monkeys ($N=50$) (Kalin et al., 1998). EEG measures were obtained during periods of manual restraint. A subsample of 15 of these monkeys were tested on two occasions four months apart. We found that the test-retest correlation for measures of prefrontal asymmetry was .62, suggesting similar stability of this metric in monkey and man. In the group of 50 animals, we also obtained measures of plasma cortisol during the early morning. We hypothesized that if individual differences in prefrontal asymmetry were associated with dispositional affective

FIGURE 79.3 Basal morning plasma cortisol from one-year-old rhesus monkeys classified as left ($N=12$), middle ($N=16$), or right ($N=11$) frontally activated based upon electrophysiological measurements. (From Kalin et al., 1998.)

style, such differences should be correlated with cortisol, since individual differences in baseline cortisol have been related to various aspects of trait-related stressful behavior and psychopathology (see, e.g., Gold, Goodwin, and Chrousos, 1988). We found that animals with right-sided prefrontal activation had higher levels of baseline cortisol than their left-frontally activated counterparts (see figure 79.3). Moreover, when blood samples were collected two years after our initial testing, animals classified as showing extreme right-sided prefrontal activation at age one year had significantly higher baseline cortisol levels when they were three years of age than animals who were classified at age one year as displaying extreme left-sided prefrontal activation. These findings indicate that individual differences in prefrontal asymmetry are present in nonhuman primates and that such differences predict biological measures that are related to affective style.

With the advent of neuroimaging, it has become possible to investigate the relation between individual differences in aspects of amygdala function and measures of affective style. We have used PET with fluorodeoxyglucose (FDG) as a tracer to investigate relations between individual differences in glucose metabolism in the amygdala and dispositional negative affect. Because the period of active uptake of tracer in the brain is approximately 30 minutes, FDG-PET is well suited to capture traitlike effects. Thus it is inherently more reliable than O15 blood-flow measures, since the FDG data reflect activity aggregated over a 30-minute period. We have used resting FDG-PET to examine individual differences in glucose metabolic rate in the amygdala and its relation to dispositional negative affect in depressed subjects (Abercrombie et al., 1998). We acquired a resting FDG-PET scan as well as a structural MR scan for

FIGURE 79.4 Scatter plot of the relation between metabolic rate in the right amygdala and dispositional negative affect. Metabolic rate in the amygdala was obtained by coregistering MRI and PET images and then drawing regions of interest (ROIs) on the MRIs around the amygdala. These ROIs were then automatically transferred to the PET images, and glucose metabolic rate for these regions was determined. ECAT and Advance refer to two different PET scanners that were used to collect the data. (From Abercrombie et al., 1998.)

each subject. The structural MR scans are used for anatomical localization by coregistering the two image sets. Thus, for each subject, we used an automated algorithm to fit the MR scan to the PET image. Regions of interest (ROIs) were then drawn on each subject's MR scan to outline the amygdala in each hemisphere. These ROIs were drawn on coronal sections of subjects' MR images, and the ROIs were then automatically transferred to the coregistered PET images. Glucose metabolism in the left and right amygdala ROIs were then extracted. The inter-rater reliability for the extracted glucose metabolic rate is highly significant with intraclass correlations between two independent raters $\geq .97$. We found that subjects with greater glucose metabolism in the right amygdala report greater dispositional negative affect on the PANAS scale (see figure 79.4). These findings indicate that individual differences in resting glucose metabolism in the amygdala are present and that they predict dispositional negative affect among depressed subjects.

In a small sample of 9 normal subjects, we have been able to examine the relation between the magnitude of MR signal change in the amygdala in response to aversive compared with neutral pictures and dispositional negative affect on the PANAS scale (Irwin et al., 1998). We correlated the average value of the pixels with the maximum Student's t from the left and right amygdala with dispositional negative affect. The correlation was $r = .75$. A pixel in the fusiform gyrus that revealed robust activation by the aversive pictures was selected as a control region. We correlated the magnitude of activation in the pixel showing the maximal response in this region to the aversive pictures with dispositional negative

affective affect and found no relation ($p > .5$). Moreover, the correlations in the amygdala and fusiform gyrus were found to be significantly different. The findings from the fMRI and PET studies of amygdala function indicate that individual differences in both tonic activation and phasic activation in response to aversive stimuli predict the intensity of dispositional negative affect.

Implications and conclusions

Earlier in this chapter, the constituents of affective style were described. We considered individual differences in threshold, peak amplitude, rise time to peak, and recovery time. Together these constitute parameters of affective chronometry and dictate important features of the time course of affective responding. Following a description of the functional neuroanatomy of the approach and withdrawal systems, individual differences in prefrontal activation asymmetry and amygdala function were discussed and their relation to affective style described. In light of this information, we now return to the question posed in the section titled "What do individual differences in asymmetric prefrontal activation reflect?"

On the basis of findings from several new studies in my laboratory, I suggest that at least one important component of what prefrontal cortex "does" in affective responding is to modulate the time course of emotional responding, particularly recovery time. There are several facts critical to making this claim. First, there are extensive reciprocal connections between amygdala and PFC, particularly the medial and orbital zones of prefrontal cortex (Amaral et al., 1992). The glutamatergic efferents from PFC likely synapse on GABA neurons (Amaral et al., 1992) and thus provide an important inhibitory input to the amygdala. Second, LeDoux and his colleagues (Morgan, Romanski, and LeDoux, 1993; but see Gewirtz, Falls, and Davis, 1997) demonstrated in rats that lesions of medial prefrontal cortex dramatically prolong the maintenance of a conditioned aversive response. In other words, animals with medial prefrontal lesions retain aversive associations for a much longer duration of time than normal animals. These findings imply that the medial PFC normally inhibits the amygdala as an active component of extinction. In the absence of this normal inhibitory input, the amygdala remains unchecked and continues to maintain the learned aversive response. Third, the data from my laboratory cited in the section that asks, "What do individual differences . . . reflect?," indicate that individual differences in prefrontal activation asymmetry significantly predict the magnitude of the poststimulus startle following removal of the variance attributable to startle

magnitude during the presentation of the emotional picture. In particular, left prefrontal activation appears to facilitate two processes simultaneously: (1) It maintains representations of behavioral-reinforcement contingencies in working memory (Thorpe et al., 1983); and (2) It inhibits the amygdala. In this way, the time course of negative affect is shortened while the time course of positive affect is accentuated. And finally, new findings using PET from my laboratory indicate that in normal subjects, glucose metabolism in left medial and lateral prefrontal cortex is strongly reciprocally associated with glucose metabolic rate in the amygdala (Abercrombie et al., 1996). Thus subjects with greater left-sided prefrontal metabolism have lower metabolic activity in their amygdala. These findings are consistent with the lesion study of LeDoux and colleagues and imply that prefrontal cortex plays an important role in modulating activity in the amygdala. At the same time, left prefrontal cortex is also likely to play a role in the maintenance of reinforcement-related behavioral approach. Perhaps the damping of negative affect and shortening of its time course facilitate the maintenance of approach-related positive affect.

Data were also presented that indicate individual differences in both tonic glucose metabolism and phasic activation in response to aversive stimuli in the amygdala. These individual differences predict dispositional negative affect. Whatever modulatory influence the prefrontal cortex might have over the amygdala, it appears that the magnitude of phasic activation of the amygdala by aversive stimuli accounts for a substantial portion of variance in self-reported dispositional negative affect, considerably more than any of our measures of prefrontal function. Thus the proximal control of dispositional negative affect is likely to be more closely associated with amygdala function than with prefrontal function.

The questions that are featured in this chapter are more tractable now than ever before. With the advent of echoplanar methods for rapid functional MR imaging, sufficient data can be collected within individuals to examine functional connections among regions hypothesized to constitute important elements of the approach and withdrawal circuits discussed earlier. Individual differences in different aspects of these systems can then be studied with greater precision. In addition, fMRI methods lend themselves to address questions related to affective chronometry. In particular, we can calculate the slope of declines in MR signal intensity following the offset of an aversive stimulus to provide an index of the rapidity of recovery from activation in select brain regions. Also, PET methods using new radioligands that permit quantification of receptor density for specific neurotrans-

mitters in different brain regions are yielding new insights directly relevant to questions about affective style (see, e.g., Farde, Gustavsson, and Jönsson, 1997). Trait-like differences in affective style are likely reflected in relatively stable differences in characteristics of the underlying neurochemical systems. Using PET to examine such individual differences promises to provide important syntheses between neurochemical and neuroanatomical approaches to understanding the biological bases of affective style.

Affective neuroscience seeks to understand the underlying proximal neural substrates of elementary constituents of emotional processing. In this chapter, I have provided a model of the functional neuroanatomy of approach and withdrawal motivational/emotional systems and illustrated the many varieties of individual differences that might occur in these systems. Research on prefrontal asymmetries associated with affective style was used to illustrate the potential promise of some initial approaches to the study of these questions. Modern neuroimaging methods used in conjunction with theoretically sophisticated models of emotion and psychopathology offer great promise in advancing our understanding of the basic mechanisms that give rise to affective style and to affective and anxiety disorders.

NOTE

1. In this initial study on the recovery function assessed with startle probe measures, we had only a single poststimulus probe at 500 ms following the offset of the picture. Readers may be surprised that the interval between the offset of the picture and the presentation of the probe was so short. However, it should be noted that these emotional pictures are not particularly intense, and so the lingering effect of emotion following the presentation of such pictures is likely not to last very long in most individuals. Future studies will probe further out following the offset of the picture. Since at most only a single probe can be presented for each picture so that habituation effects are minimized, each new probe position requires a substantial increase in the overall number of pictures presented. There is a finite limit to the number of pictures contained in the IAPS. Even more importantly, we have found that it is critical to keep the picture viewing period to well under one hour to minimize fatigue and boredom.

Introduction

LEDA COSMIDES AND JOHN TOOBY

Most cognitive neuroscientists recognize the need for reliable sources of theoretical guidance. Many have taken a bottom-up approach, turning to cellular and molecular neurobiology. But there also is a top-down approach, which can be equally or more informative. Knowledge of evolved function can be used to identify functional units within the brain and mind and to guide investigation into their designs. Despite their sustained record of success in other areas of biology, evolutionary methods are only beginning to be understood or applied in the cognitive neurosciences. This section outlines this approach and illustrates its use.

Dissection implies function

When anatomists dissect an organism, they do not cut it randomly. Dissection—whether done by a real scalpel or a conceptual one—implies the search for functional units. Because the brain's function is to process information, correctly dissecting its neural architecture into functional units depends on correctly dissecting its cognitive architecture into corresponding, functionally meaningful computational units. Because human and nonhuman brains were constructed by the evolutionary process, these units were organized according to an underlying evolutionary logic—a logic that must be grasped if this process of dissection is to be successful. Because knowledge of adaptive problems and models

of evolved functions provides the functional engineering specifications to which human and nonhuman brains were built to conform, evolutionary biology and psychology can help researchers to isolate, identify, activate, and map the important, functional design features of the cognitive architecture that otherwise would be lost among the maze of functionally irrelevant physical concomitants in which they are embedded (see chapter 80 for an overview of issues).

The cross-species diversity of brain architectures

Advocates of the bottom-up approach argue that the findings of neuroscience will place strong constraints on theory formation at the cognitive level. Such knowledge is very valuable, and it undoubtedly will contribute a great deal to theory formation in the long run. But one reason why many neglect the analysis of evolved function is because they believe that neural constraints will be sufficient for developing cognitive theories. This cannot be true.

Consider the fact that there are bird species that navigate by the stars or by the Earth's magnetic field, bats that echolocate and engage in reciprocal blood sharing, bees that compute the variance of flower patches and discriminate classes of kin, spiders that spin webs and extract social information from web movement, ant species that farm or defend host trees or dead reckon, elephant seals that forage hundreds of feet underwater, monogamous gibbons, polygynous gorillas, polyandrous seahorses, sex-changing coral reef fish, mole rats that form social-insect-like colonies, and so on. There are millions of animal species on earth, each with a different set of cognitive programs—programs that often are radically different from each other, even in closely related species. The same basic neural tissue embodies all of these programs, and it could support innumerable others as well. Facts about the properties of neurons, neurotransmitters, and cellular development cannot tell you which of these billions of programs will develop reliably in the human (or, e.g., the rhesus) mind.

Even if all neural computation turned out to be the expression of universally shared processes at the cellular level, it is the higher-order arrangement of neurons—into birdsong templates or web-spinning programs or facial emotion display programs—that matters computationally. The idea that low-level neuroscience unassisted can produce models of cognitive mechanisms is a physicalist expression of the ethologically naïve associationist doctrine that all animal brains are essentially the same (see chapter 81 [associationism] and chapter 84 and Preuss, 1995 [comparative neuroanatomy]). A related assumption—that a few computational principles underlie most

mechanisms in the brains of animal species—organizes the thinking of neoassociationists and connectionists (e.g., Quartz and Sejnowski, 1997). If this were true, then the adaptive problems encountered by species ancestrally would indeed be irrelevant: The neoassociationist assumption is that evolution selected for general-purpose brains that solved most or all problems using methods applicable to the broadest and most general class of problems. In this view, brains lack specializations reflecting the specific demands of a species' particular way of life. A logical corollary of this view is that all information necessary to solve problems must be acquirable ontogenetically, through the senses, because it is not being supplied phylogenetically, in the form of evolutionarily organized specializations.

The challenge from evolutionary biology

It is difficult to reconcile this view with the mass of data accumulated by behavioral ecologists and evolutionarily oriented psychologists about behavioral diversity and the array of problems that organisms are known to solve. By using theories of adaptive function to guide their investigations, behavioral ecologists have been able to document a range of animal behavior that is breathtaking in its adaptive problem-solving sophistication and whose generation often requires information that could not be supplied ontogenetically or perceptually. There is, for example, no perceptual data in the ontogenetic environment that specifies that a male langur monkey who has taken over a troop should kill all the infants born within the following several months whereas a titi monkey should not; or that a female ground squirrel should give more alarm calls when the neighboring ground squirrels are her sisters than when they are not, and so on. These rules must be in the adaptations, because they are not in stimuli.

Equally important, specialization of circuitry often greatly increases computational efficiency, and endows architectures with the capacity to solve problems that could not be solved at all by general-purpose methods, making architectures that operate primarily through general-purpose methods uncompetitive and unlikely to evolve. These and many other converging lines of evidence and argument collectively contradict the view that a few general-purpose computational principles could explain known behavioral phenomena or be capable of solving many of the adaptive problems that humans and other species faced during their evolutionary histories (Tooby and Cosmides, 1992). As Gallistel shows (chapter 81), even in the case of animal learning—the set of phenomena that associationism was explicitly developed to handle—associationistic theories are theo-

retical and empirical failures, incapable of being made consistent with the data, much less of accounting for it.

To free theorizing in cognitive neuroscience from the Procrustean bed of a one-solution-fits-all-problems approach, and to clear the ground for a new generation of theories of heterogeneous functional specializations, it would be helpful if cognitive neuroscientists became aware of the truly diverse nature of adaptive problems organisms solve. Toward this end, this section includes several chapters about nonhumans to give a textured feel for the kinds of adaptive tasks that other animals' minds are able to solve quickly and efficiently. These include the chapters by Fernald and White (chapter 82) on the social behavior of territorial fish, by Sherry (chapter 83) on the spatial cognition of parasitic cowbirds, polygynous meadow voles and monogamous pine voles, and by Gallistel (chapter 81) on dead-reckoning in ants, computation of the solar ephemeris by bees, and classical conditioning in pigeons and rats (see also Gaulin, 1995; Daly and Wilson, 1995). In every case in which the computational processes are known in any detail, they have turned out to be narrowly tailored to the demands of solving specific adaptive problems.

Constraints on hypotheses

Because efficient computational designs will almost always be specialized to fit the particular nature of the problems they solve, an investigation into the nature of adaptive problems is a very productive research strategy. For any given adaptive problem, only a highly restricted class of candidate program designs has the properties required to solve it. Thus, knowledge of the structure of the adaptive problem informs the researcher about large numbers of probable design features, greatly facilitating the construction of experiments that can probe for their presence.

For this reason, cognitive neuroscientists stand to profit greatly from formally describing the problems that the human cognitive architecture evolved to solve. The intuitive conceptions of function that are widely used instead—such as “learning” and “memory”—are simply too broad to be useful. As Gallistel (chapter 81) points out:

It is odd but true that most past and contemporary theorizing about learning does not assume that learning mechanisms are adaptively specialized for the solution of particular kinds of problems. Most theorizing assumes that there is a general purpose learning process in the brain, a process adapted only to solving the problem of learning. There is no attempt to formalize what the problem of learning is and thereby determine whether it can in fact be conceived of as a single or uniform

problem. From a biological perspective, this assumption is equivalent to assuming that there is a general purpose sensory organ, which solves the problem of sensing.

In his chapter, Gallistel analyzes various learning problems solved by desert ants, bees, pigeons, and other animals, showing that (1) they are incommensurate; (2) each is solved by a different computational machine that is specialized for that task; and (3) associative theories of learning are incapable of explaining the animal learning data. According to Gallistel, there is no evidence in any species supporting the existence of the associative bond. If he is correct, then neuroscientists who hope to unlock the secrets of learning and memory by looking for the neural basis of the associative bond have had their time wasted by evolutionarily uninformed models of natural computational systems. This underlines how good research at the neural level depends on having a correct characterization of the computational level, which in turn depends on understanding the evolutionary principles responsible for organic design.

Humans also evolved

The chapters dealing with humans (chapters 83 and 85–87) also take a top-down approach. Although the hypothesis that there might be cognitive specializations for navigating the social world was once considered intuitively implausible by many, the adaptive problems posed by social life are both complex and have enormous fitness consequences. This led evolutionarily informed researchers to research the hypothesis that human brains—like those of other animals—contain a number of cognitive adaptations for understanding and negotiating social life. Following this logic, Baron-Cohen, Cosmides and Tooby, and Leslie have been finding evidence for domain-specific mechanisms specialized for reasoning about the contents of other minds and about cooperation. This research not only illuminates the computational structure of social cognitive adaptations, but it also illuminates the nature of neurological disorders, such as autism, which appear to involve selective deficits in particular computational subcomponents of social adaptations.

Toward Mapping the Evolved Functional Organization of Mind and Brain

JOHN TOOBY AND LEDA COSMIDES

ABSTRACT The human brain is a biological system produced by the evolutionary process, and thus, cognitive neuroscience is itself a branch of evolutionary biology. Accordingly, cognitive neuroscientists can benefit by learning about and applying the technical advances made in modern evolutionary biology. Among other things, evolutionary biology can supply researchers with (1) the biologically rigorous concept of function appropriate to neural and cognitive systems, (2) a growing list of the specialized functions the human brain evolved to perform, and (3) the ability to distinguish the narrowly functional aspects of the neural and cognitive architecture that are responsible for its organization from the much larger set of properties that are by-products or noise. With these and other tools, researchers can construct experimental stimuli and tasks that activate and are meaningful to functionally dedicated subunits of the brain. The brain is comprised of many such subunits: evolutionarily meaningful stimuli and tasks are far more likely than arbitrary ones to elicit responses that can illuminate their complex functional organization.

Nothing in biology makes sense except in the light of evolution.
— T. Dobzhansky

It is the theory which decides what we can observe.
— A. Einstein

Seeing with new eyes: Toward an evolutionarily informed cognitive neuroscience

The task of cognitive neuroscience is to map the information-processing structure of the human mind and to discover how this computational organization is implemented in the physical organization of the brain. The central impediment to progress is obvious: The human brain is, by many orders of magnitude, the most complex system that humans have yet investigated. Purely as a physical system, the vast intricacy of chemical and electrical interactions among hundreds of billions of neurons and glial cells defeats any straightforward attempt to build a comprehensive model, as one might at-

tempt to do with particle collisions, geological processes, protein folding, or host-parasite interactions. Combinatorial explosion makes the task of elucidating the brain's computational structure even more overwhelming: There is an indefinitely large number of specifiable inputs, measurable outputs, and possible relationships between them. Even worse, no one yet knows with certainty how computations are physically realized. They depend on individuated events within the detailed structure of neural microcircuitry largely beyond the capacity of current technologies to observe or resolve. Finally, the underlying logic of the system has been obscured by the torrent of recently generated data.

Historically, however, well-established theories from one discipline have functioned as organs of perception for others (e.g., statistical mechanics for thermodynamics). They allow new relationships to be observed, and make visible elegant systems of organization that had previously eluded detection. It seems worth exploring whether evolutionary biology could provide a rigorous metatheoretical framework for the brain sciences, as they have recently begun to do for psychology (Shepard, 1984, 1987a, 1987b; Gallistel, 1990; Cosmides and Tooby, 1987; Pinker, 1994, 1997; Marr 1982; Tooby and Cosmides, 1992).

Cognitive neuroscience began with the recognition that the brain is an organ designed to process information, and that studying it as such would offer important new insights. Cognitive neuroscientists also recognize that the brain is an evolved system, but few realize that anything follows from this second fact. Yet these two views of the brain are intimately related and, when considered jointly, can be very illuminating.

Why brains exist

The brain is an organ of computation that was built by the evolutionary process. To say that the brain is an organ of computation means that (1) its physical structure embodies a set of programs that process information, and (2) that physical structure is there *because* it embodies these programs. To say that the brain was built

JOHN TOOBY Center for Evolutionary Psychology and Department of Anthropology, University of California, Santa Barbara, Calif.

LEDA COSMIDES Center for Evolutionary Psychology and Department of Psychology, University of California, Santa Barbara, Calif.

by the evolutionary process means that its functional components—its programs—are there *because* they solved a particular problem-type in the past. In systems designed by natural selection, function determines structure.

Among living things, there are whole kingdoms filled with organisms that lack brains (plants, Monera, fungi). The sole reason that evolution introduced brains into the designs of some organisms—the reason brains exist at all—is because brains performed computations that regulated these organisms' internal processes and external activities in ways that promoted their fitness. For a randomly generated modification in design to be selected—that is, for a mutation to be incorporated by means of a nonrandom process into a species-typical brain design—it had to improve the ability of organisms to solve adaptive problems. That is, the modification had to have a certain kind of effect: It had to improve the organisms' performance of some activity that systematically enhanced the propagation of that modification, summed across the species' range and across many generations. This means that the design of the circuits, components, systems, or modules that make up our neural architecture must reflect, to an unknown but high degree, (1) the computational task demands inherent in the performance of those ancestral activities and (2) the evolutionarily long-enduring structure of those task environments (Marr, 1982; Shepard, 1987a; Tooby and Cosmides, 1992).

Activities that promoted fitness in hominid ancestral environments differ in many ways from activities that capture our attention in the modern world, and they were certainly performed under radically different circumstances. (Consider: hunting *vs.* grocery shopping; walking everywhere *vs.* driving and flying; cooperating within a social world of ~200 relatives and friends *vs.* 50,000 strangers in a medium-sized city). The design features of the brain were built to specifications inherent in ancestral adaptive problems and selection pressures, often resulting in talents or deficits that seem out of place or irrational in our world. A baby cries—alerting her parents—when she is left to sleep alone in the dark, not because hyenas roam her suburban household, but because her brain is designed to keep her from being eaten under the circumstances in which our species evolved.

There is no single algorithm or computational procedure that can solve every adaptive problem (Cosmides and Tooby, 1987; Tooby and Cosmides, 1990a, 1992). The human mind (it will turn out) is composed of many different programs for the same reason that a carpenter's toolbox contains many different tools: Different problems require different solutions. To reverse-engineer the

brain, one needs to discover functional units that are native to its organization. To do this, it is useful to know, as specifically as possible, what the brain is for—which specific families of computations it was built to accomplish and what counted as a biologically successful outcome for each problem-type. The answers to this question must be phrased in computational terms because that is the only language that can capture or express the functions that neural properties were naturally selected to embody. They must also refer to the ancestral activities, problems, selection pressures, and environments of the species in question because jointly these define the computational problems each component was configured to solve (Cosmides and Tooby 1987; Tooby and Cosmides, 1990a, 1992).

For these reasons, evolutionary biology, biological anthropology, and cognitive psychology (when integrated, called *evolutionary psychology*) have the potential to supply to cognitive neuroscientists what might prove to be a key missing element in their research program: a partial list of the native information-processing functions that the human brain was built to execute, as well as clues and principles about how to discover or evaluate adaptive problems that might be proposed in the future.

Just as the fields of electrical and mechanical engineering summarize our knowledge of principles that govern the design of human-built machines, the field of evolutionary biology summarizes our knowledge of the engineering principles that govern the design of organisms, which can be thought of as machines built by the evolutionary process (for overviews, see Daly and Wilson, 1984; Dawkins, 1976, 1982, 1986; Krebs and Davies, 1997). Modern evolutionary biology constitutes, in effect, a foundational “organism design theory” whose principles can be used to fit together research findings into coherent models of specific cognitive and neural mechanisms (Tooby and Cosmides, 1992). To apply these theories to a particular species, one integrates analyses of selection pressures with models of the natural history and ancestral environments of the species. For humans, the latter are provided by hunter-gatherer studies, biological anthropology, paleoanthropology, and primatology (Lee and DeVore, 1968).

First principles: Reproduction, feedback, and the antientropic construction of organic design

Within an evolutionary framework, an organism can be described as a self-reproducing machine. From this perspective, the defining property of life is the presence in a system of “devices” (organized components) that cause the system to construct new and similarly reproducing

systems. From this defining property—self-reproduction—the entire deductive structure of modern Darwinism logically follows (Dawkins, 1976; Williams, 1985; Tooby and Cosmides, 1990a). Because the replication of the design of the parental machine is not always error free, randomly modified designs (i.e., mutants) are introduced into populations of reproducers. Because such machines are highly organized so that they cause the otherwise improbable outcome of constructing offspring machines, most random modifications interfere with the complex sequence of actions necessary for self-reproduction. Consequently, such modified designs will tend to remove themselves from the population—a case of negative feedback.

However, a small residual subset of design modifications will, by chance, happen to constitute improvements in the design's machinery for causing its own reproduction. Such improved designs (by definition) cause their own increasing frequency in the population—a case of positive feedback. This increase continues until (usually) such modified designs outreproduce and thereby replace all alternative designs in the population, leading to a new species-standard design. After such an event, the population of reproducing machines is different from the ancestral population: The population- or species-standard design has taken a step “uphill” toward a greater degree of functional organization for reproduction than it had previously. This spontaneous feedback process—natural selection—causes functional organization to emerge *naturally*, that is, without the intervention of an intelligent “designer” or supernatural forces.

Over the long run, down chains of descent, this feedback cycle pushes designs through state-space toward increasingly well-organized—and otherwise improbable—functional arrangements (Dawkins 1986; Williams, 1966, 1985). These arrangements are functional in a specific sense: the elements are improbably well organized to cause their own reproduction in the environment in which the species evolved. Because the reproductive fates of the inherited traits that coexist in the same organism are linked together, traits will be selected to enhance each other's functionality (however, see Cosmides and Tooby, 1981, and Tooby and Cosmides, 1990a, for the relevant genetic analysis and qualifications). As design features accumulate, they will tend to sequentially fit themselves together into increasingly functionally elaborated machines for reproduction, composed of constituent mechanisms—called *adaptations*—that solve problems that either are necessary for reproduction or increase its likelihood (Darwin, 1859; Dawkins, 1986; Thornhill, 1991; Tooby and Cosmides, 1990a; Williams, 1966, 1985). Significantly, in species like humans, genetic processes ensure that complex adaptations virtu-

ally always are species-typical (unlike nonfunctional aspects of the system). This means that *functional* aspects of the architecture will tend to be universal at the genetic level, even though their expression may often be sex or age limited, or environmentally contingent (Tooby and Cosmides, 1990b).¹

Because design features are embodied in individual organisms, they can, generally speaking, propagate themselves in only two ways: by solving problems that increase the probability that offspring will be produced either by the organism they are situated in or by that organism's kin (Hamilton, 1964; Williams and Williams, 1957; however, see Cosmides and Tooby, 1981, and Haig, 1993, for intragenomic methods). An individual's relatives, by virtue of having descended from a recent common ancestor, have an increased likelihood of having the same design feature as compared to other conspecifics. This means that a design modification in an individual that causes an increase in the reproductive rate of that individual's kin will, by so doing, tend to increase its own frequency in the population. Accordingly, design features that promote both direct reproduction and kin reproduction, and that make efficient trade-offs between the two, will replace those that do not. To put this in standard biological terminology, design features are selected to the extent that they promote their inclusive fitness (Hamilton, 1964).

In addition to selection, mutations can become incorporated into species-typical designs by means of chance processes. For example, the sheer impact of many random accidents may cumulatively propel a useless mutation upward in frequency until it crowds out all alternative design features from the population. Clearly, the presence of such a trait in the architecture is not explained by the (nonexistent) functional consequences that it had over many generations on the design's reproduction; as a result, chance-injected traits will not tend to be coordinated with the rest of the organism's architecture in a functional way.

Although such chance events play a restricted role in evolution and explain the existence and distribution of many simple and trivial properties, organisms are not primarily chance agglomerations of stray properties. Reproduction is a highly improbable outcome in the absence of functional machinery designed to bring it about, and only designs that retain all the necessary machinery avoid being selected out. To be invisible to selection—and, therefore, not organized by it—a modification must be so minor that its effects on reproduction are negligible. As a result, chance properties do indeed drift through the standard designs of species in a random way, but they are unable to account for the complex organized design in organisms and are, correspondingly,

usually peripheralized into those aspects that do not make a significant impact on the functional operation of the system (Tooby and Cosmides, 1990a, 1990b, 1992). Random walks do not systematically build intricate and improbably functional arrangements, such as the visual system, the language faculty, face recognition programs, emotion recognition modules, food aversion circuits, cheater detection devices, or motor control systems, for the same reason that wind in a junkyard does not assemble airplanes and radar.

Brains are composed primarily of adaptive problem-solving devices

In fact, natural selection is the only known cause of and explanation for complex functional design in organic systems. Hence, all naturally occurring functional organization in organisms should be ascribed to its operation, and hypotheses about function are likely to be correct only if they are the kinds of functionality that natural selection produces.

This leads to the most important point for cognitive neuroscientists to abstract from modern evolutionary biology: Although not everything in the designs of organisms is the product of selection, all complex functional organization is. Indeed, selection can only account for functionality of a very narrow kind: approximately, design features organized to promote the reproduction of an individual and his or her relatives in ancestral environments (Williams, 1966; Dawkins, 1986). Fortunately for the modern theory of evolution, the only naturally occurring complex functionality that ever has been documented in undomesticated plants, animals, or other organisms is functionality of just this kind, along with its derivatives and by-products.

This has several important implications for cognitive neuroscientists:

1. *Technical definition of function.* In explaining or exploring the reliably developing organization of a cognitive device, the *function* of a design refers solely to how it systematically caused its own propagation in ancestral environments. It does not validly refer to any intuitive or folk definitions of function such as “contributing to personal goals,” “contributing to one’s well-being,” or “contributing to society.” These other kinds of usefulness may or may not exist as side effects of a given evolved design, but they can play no role in explaining how such designs came into existence or why they have the organization that they do.

It is important to bear in mind that the evolutionary standard of functionality is entirely independent of any ordinary human standard of desirability, social value, morality, or health (Cosmides and Tooby, in press).

2. *Adapted to the past.* The human brain, to the extent that it is organized to do anything functional at all, is organized to construct information, make decisions, and generate behavior that would have tended to promote inclusive fitness in the ancestral environments and behavioral contexts of Pleistocene hunter-gatherers and before. (The preagricultural world of hunter-gatherers is the appropriate ancestral context because natural selection operates far too slowly to have built complex information-processing adaptations to the post-hunter-gatherer world of the last few thousand years.)

3. *No evolved “reading modules.”* The problems that our cognitive devices are designed to solve do not reflect the problems that our modern life experiences lead us to see as normal, such as reading, driving cars, working for large organizations, reading insurance forms, learning the oboe, or playing Go. Instead, they are the odd and seemingly esoteric problems that our hunter-gatherer ancestors encountered generation after generation over hominid evolution. These include such problems as foraging, kin recognition, “mind reading” (i.e., inferring beliefs, desires, and intentions from behavior), engaging in social exchange, avoiding incest, choosing mates, interpreting threats, recognizing emotions, caring for children, regulating immune function, and so on, as well as the already well-known problems involved in perception, language acquisition, and motor control.

4. *Side effects are personally important but scientifically misleading.* Although our architectures may be capable of performing tasks that are “functional” in the (nonbiological) sense that we may value them (e.g., weaving, playing piano), these are incidental side effects of selection for our Pleistocene competencies—just as a machine built to be a hair-dryer can, incidentally, dehydrate fruit or electrocute. But it will be difficult to make sense of our cognitive mechanisms if one attempts to interpret them as devices designed to perform functions that were not selectively important for our hunter-gatherer ancestors, or if one fails to consider the adaptive functions these abilities are side effects of.

5. *Adaptationism provides new techniques and principles.* Whenever one finds better-than-chance functional organization built into our cognitive or neural architecture, one is looking at adaptations—devices that acquired their distinctive organization from natural selection acting on our hunter-gatherer or more distant primate ancestors. Reciprocally, when one is searching for intelligible functional organization underlying a set of cognitive or neural phenomena, one is far more likely to discover it by using an adaptationist framework for organizing observations because adaptive organization is the only kind of functional organization that is there to be found.

Because the reliably developing mechanisms (i.e., circuits, modules, functionally isolable units, mental organs, or computational devices) that cognitive neuroscientists study are evolved adaptations, all the biological principles that apply to adaptations apply to cognitive devices. This connects cognitive neuroscience and evolutionary biology in the most direct possible way. This conclusion should be a welcome one because it is the logical doorway through which a very extensive body of new expertise and principles can be made to apply to cognitive neuroscience, stringently constraining the range of valid hypotheses about the functions and structures of cognitive mechanisms. Because cognitive neuroscientists are usually studying adaptations and their effects, they can supplement their present research methods with carefully derived adaptationist analytic tools.

6. *Ruling out and ruling in.* Evolutionary biology gives specific and rigorous content to the concept of function, imposing strict rules on its use (Williams, 1966; Dawkins, 1982, 1986). This allows one to rule out certain hypotheses about the proposed function of a given cognitive mechanism. But the problem is not just that cognitive neuroscientists sometimes impute functions that they ought not to. An even larger problem is that many fail to impute functions that they ought to. For example, an otherwise excellent recent talk by a prominent cognitive neuroscientist began with the claim that one would not expect jealousy to be a “primary” emotion—that is, a universal, reliably developing part of the human neural architecture (in contrast to others, such as disgust or fear). Yet there is a large body of theory in evolutionary biology—sexual selection theory—that predicts that sexual jealousy will be widespread in species with substantial parental investment in offspring (particularly in males); behavioral ecologists have documented mate-guarding behavior (behavior designed to keep sexual competitors away from one’s mate) in a wide variety of species, including various birds, fish, insects, and mammals (Krebs and Davies, 1997; Wilson and Daly, 1992); male sexual jealousy exists in every documented human culture (Daly et al., 1982; Wilson and Daly, 1992); it is the major cause of spousal homicides (Daly and Wilson, 1988), and in experimental settings, the design features of sexual jealousy have been shown to differ between the sexes in ways that reflect the different adaptive problems faced by ancestral men and women (Buss, 1994). From the standpoint of evolutionary biology and behavioral ecology, the hypothesis that sexual jealousy is a primary emotion—more specifically, the hypothesis that the human brain includes neurocognitive mechanisms whose function is to regulate the conditions under which sexual jealousy is expressed and what its cognitive and behav-

ioral manifestations will be like—is virtually inescapable (for an evolutionary/cognitive approach to emotions, see Tooby and Cosmides, 1990a, 1990b). But if cognitive neuroscientists are not aware of this body of theory and evidence, they will not design experiments capable of revealing such mechanisms.

7. *Biological parsimony, not physics parsimony.* The standard of parsimony imported from physics, the traditional philosophy of science, or from habits of economical programming is inappropriate and misleading in biology, and hence, in neuroscience and cognitive science, which study biological systems. The evolutionary process never starts with a clean work board, has no foresight, and incorporates new features solely on the basis of whether they lead to systematically enhanced propagation. Indeed, when one examines the brain, one sees an amazingly heterogeneous physical structure. A correct theory of evolved cognitive functions should be no less complex and heterogeneous than the evolved physical structure itself and should map on to the heterogeneous set of recurring adaptive tasks faced by hominid foragers over evolutionary time. Theories of engineered machinery involve theories of the subcomponents. One would not expect that a general, unified theory of robot or automotive mechanism could be accurate.

8. *Many cognitive adaptations.* Indeed, analyses of the adaptive problems humans and other animals must have regularly solved over evolutionary time suggest that the mind contains a far greater number of functional specializations than is traditionally supposed, even by cognitive scientists sympathetic to “modular” approaches. From an evolutionary perspective, the human cognitive architecture is far more likely to resemble a confederation of hundreds or thousands of functionally dedicated computers, designed to solve problems endemic to the Pleistocene, than it is to resemble a single general purpose computer equipped with a small number of domain-general procedures, such as association formation, categorization, or production rule formation (for discussion, see Cosmides and Tooby, 1987, 1994; Gallistel, 1990; Pinker, 1997; Sperber, 1994; Symons, 1987; Tooby and Cosmides, 1992; see also chapter 81 of this volume).

9. *Cognitive descriptions are necessary.* Understanding the neural organization of the brain depends on understanding the functional organization of its computational relationships or cognitive devices. The brain originally came into existence and accumulated its particular set of design features only because these features functionally contributed to the organism’s propagation. This contribution—that is, the evolutionary function of the brain—is obviously the adaptive regulation of behavior and physiology *on the basis of information* derived

from the body and from the environment. The brain performs no significant mechanical, metabolic, or chemical service for the organism—its function is purely informational, computational, and regulatory in nature. Because the function of the brain is informational in nature, its precise functional organization can only be accurately described in a language that is capable of expressing its informational functions—that is, in cognitive terms, rather than in cellular, anatomical, or chemical terms. Cognitive investigations are not some soft, optional activity that goes on only until the “real” neural analysis can be performed. Instead, the mapping of the computational adaptations of the brain is an unavoidable and indispensable step in the neuroscience research enterprise. It must proceed in tandem with neural investigations and provides one of the primary frameworks necessary for organizing the body of neuroscience results.

The reason is straightforward. Natural selection retained neural structures on the basis of their ability to create adaptively organized relationships between information and behavior (e.g., the sight of a predator activates inference procedures that cause the organism to hide or flee) or between information and physiology (e.g., the sight of a predator increases the organism’s heart rate, in preparation for flight). Thus, it is the information-processing structure of the human psychological architecture that has been functionally organized by natural selection, and the neural structures and processes have been organized insofar as they physically realize this cognitive organization. Brains exist and have the structure that they do because of the computational requirements imposed by selection on our ancestors. The adaptive structure of our computational devices provides a skeleton around which a modern understanding of our neural architecture should be constructed.

Brain architectures consist of adaptations, by-products, and random effects

To understand the human (or any living species’) computational or neural architecture is a problem in reverse engineering: We have working exemplars of the design in front of us, but we need to organize our observations of these exemplars into a systematic functional and causal description of the design. One can describe and decompose brains into properties according to any of an infinite set of alternative systems, and hence there are an indefinitely large number of cognitive and neural phenomena that could be defined and measured. However, describing and investigating the architecture in terms of its adaptations is a useful place

to begin, because (1) the adaptations are the cause of the system’s organization (the reason for the system’s existence), (2) organisms, properly described, consist largely of collections of adaptations (evolved problem-solvers), (3) an adaptationist frame of reference allows cognitive neuroscientists to apply to their research problems the formidable array of knowledge that evolutionary biologists have accumulated about adaptations, (4) all of the complex functionally organized subsystems in the architecture are adaptations, and (5) such a frame of reference permits the construction of economical and principled models of the important features of the system, in which the wealth of varied phenomena fall into intelligible, functional, and predictable patterns. As Ernst Mayr put it, summarizing the historical record, “the adaptationist question, ‘What is the function of a given structure or organ?’ has been for centuries the basis for every advance in physiology” (Mayr, 1983, p. 32). It should prove no less productive for cognitive neuroscientists. Indeed, all of the inherited design features of organisms can be partitioned into three categories: (1) adaptations (often, although not always, complex); (2) the by-products or concomitants of adaptations; and (3) random effects. Chance and selection, the two components of the evolutionary process, explain different types of design properties in organisms, and all aspects of design must be attributed to one of these two forces. The conspicuously distinctive cumulative impacts of chance and selection allow the development of rigorous standards of evidence for recognizing and establishing the existence of adaptations and distinguishing them from the nonadaptive aspects of organisms caused by the nonselectionist mechanisms of evolutionary change (Williams, 1966, 1985; Pinker and Bloom, 1992; Symons, 1992; Thornhill, 1991; Tooby and Cosmides, 1990a, 1990b, 1992; Dawkins, 1986).

DESIGN EVIDENCE Adaptations are systems of properties (“mechanisms”) crafted by natural selection to solve the specific problems posed by the regularities of the physical, chemical, developmental, ecological, demographic, social, and informational environments encountered by ancestral populations during the course of a species’ or population’s evolution (table 80.1). Adaptations are recognizable by “evidence of special design” (Williams, 1966)—that is, by recognizing certain features of the evolved species-typical design of an organism “as components of some special problem-solving machinery” (Williams, 1985, p. 1). Moreover, they are so well organized and such good engineering solutions to adaptive problems that a chance coordination between problem and solution is effectively ruled out

TABLE 80.1
The formal properties of an adaptation

An adaptation is:

1. A cross-generationally recurring set of characteristics of the phenotype
2. that is reliably manufactured over the developmental life history of the organism,
3. according to instructions contained in its genetic specification,
4. in interaction with stable and recurring features of the environment (i.e., it reliably develops normally when exposed to normal ontogenetic environments),
5. whose genetic basis became established and organized in the species (or population) over evolutionary time, because
6. the set of characteristics systematically interacted with stable and recurring features of the ancestral environment (the "adaptive problem"),
7. in a way that systematically promoted the propagation of the genetic basis of the set of characteristics better than the alternative designs existing in the population during the period of selection. This promotion virtually always takes place through enhancing the reproduction of the individual bearing the set of characteristics, or the reproduction of the relatives of that individual.

Adaptations. The most fundamental analytic tool for organizing observations about a species' functional architecture is the definition of an adaptation. To function, adaptations must evolve such that their causal properties rely on and exploit these stable and enduring statistical structural regularities in the world, and in other parts of the organism. Things worth noticing include the fact that an adaptation (such as teeth or breasts) can develop at any time during the life cycle, and need not be present at birth; an adaptation can express itself differently in different environments (e.g., speaks English, speaks Tagalog); an adaptation is not just any individually beneficial trait, but one built over evolutionary time and expressed in many individuals; an adaptation may not be producing functional outcomes currently (e.g., agoraphobia), but only needed to function well in ancestral environments; finally, an adaptation (like every other aspect of the phenotype) is the product of gene-environment interaction. Unlike many other phenotypic properties, however, it is the result of the interaction of the species-standard set of genes with those aspects of the environment that were present and relevant during the species' evolution. For a more extensive definition of the concept of adaptation, see Tooby and Cosmides, 1990b, 1992.

as a counter-hypothesis. Standards for recognizing special design include whether the problem solved by the structure is an evolutionarily long-standing adaptive problem, and such factors as economy, efficiency, complexity, precision, specialization, and reliability, which, like a key fitting a lock, render the design too good a solution to a defined adaptive problem to be coinci-

dence (Williams, 1966). Like most other methods of empirical hypothesis testing, the demonstration that something is an adaptation is always, at core, a probability assessment concerning how likely a set of events is to have arisen by chance alone. Such assessments are made by investigating whether there is a highly non-random coordination between the recurring properties of the phenotype and the structured properties of the adaptive problem, in a way that meshed to promote fitness (genetic propagation) in ancestral environments (Tooby and Cosmides, 1990b, 1992). For example, the lens, pupil, iris, retina, visual cortex, and other parts of the eye are too well coordinated, both with each other and with features of the world, such as the properties of light, optics, geometry, and the reflectant properties of surfaces, to have co-occurred by chance. In short, like the functional aspects of any other engineered system, they are recognizable as adaptations for analyzing scenes from reflected light by their organized and functional relationships to the rest of the design and to the structure of the world.

In contrast, concomitants or by-products of adaptations are those properties of the phenotype that do not contribute to functional design per se, but that happen to be coupled to properties that are. Consequently, they were dragged along into the species-typical architecture because of selection for the functional design features to which they are linked. For example, bones are adaptations, but the fact that they are white is an incidental by-product. Bones were selected to include calcium because it conferred hardness and rigidity to the structure (and was dietarily available), and it simply happens that alkaline earth metals appear white in many compounds, including the insoluble calcium salts that are a constituent of bone. From the point of view of functional design, by-products are the result of "chance," in the sense that the process that led to their incorporation into the design was blind to their consequences (assuming that they were not negative). Accordingly, such by-products are distinguishable from adaptations by the fact that they are not complexly arranged to have improbably functional consequences (e.g., the whiteness of bone does nothing for the vertebrae).

In general, by-products will be far less informative as a focus of study than adaptations because they are consequences and not causes of the organization of the system (and hence are functionally arbitrary, unregulated, and may, for example, vary capriciously between individuals). Unfortunately, unless researchers actively seek to study organisms in terms of their adaptations, they usually end up measuring and investigating arbitrary and random admixtures of functional and functionless aspects of organisms, a situation that hampers the discovery of

the underlying organization of the biological system. We do not yet, for example, even know which exact aspects of the neuron are relevant to its function and which are by-products, so many computational neuroscientists may be using a model of the neuron that is wildly inaccurate.

Finally, entropic effects of many types are always acting to introduce disorder into the design of organisms. Traits introduced by accident or by evolutionary random walks are recognizable by the lack of coordination that they produce within the architecture or between the architecture and the environment, as well as by the fact that they frequently cause uncalibrated variation between individuals. Examples of such entropic processes include genetic mutation, recent change in ancestrally stable environmental features, and developmentally anomalous circumstances.

How well-engineered are adaptations?

The design of our cognitive and neural mechanisms should only reflect the structure of the adaptive problems that our ancestors faced to the extent that natural selection is an effective process. Is it one? How well or poorly engineered are adaptations? Some researchers have argued that evolution primarily produces inept designs, because selection does not produce perfect optimality (Gould and Lewontin, 1979). In fact, evolutionary biologists since Darwin have been well aware that selection does not produce perfect designs (Darwin, 1859; Williams, 1966; Dawkins, 1976, 1982, 1986; for a recent convert from the position that organisms are optimally designed to the more traditional adaptationist position, see Lewontin, 1967, 1979; see Dawkins, 1982, for an extensive discussion of the many processes that prevent selection from reaching perfect optimality). Still, because natural selection is a hill-climbing process that tends to choose the best of the variant designs that actually appear, and because of the immense numbers of alternatives that appear over the vast expanse of evolutionary time, natural selection tends to cause the accumulation of very well-engineered functional designs.

Empirical confirmation can be gained by comparing how well evolved devices and human engineered devices perform on evolutionarily recurrent adaptive problems (as opposed to arbitrary, artificial modern tasks, such as chess). For example, the claim that language competence is a simple and poorly engineered adaptation cannot be taken seriously, given the total amount of time, engineering, and genius that has gone into the still unsuccessful effort to produce artificial systems that can remotely approach—let alone equal—human speech per-

ception, comprehension, acquisition, and production (Pinker and Bloom, 1992).

Even more strikingly, the visual system is composed of collections of cognitive adaptations that are well-engineered products of the evolutionary process, and although they may not be “perfect” or “optimal”—however these somewhat vague concepts may be interpreted—they are far better at vision than any human-engineered system yet developed.

Wherever the standard of biological functionality can be clearly defined—semantic induction, object recognition, color constancy, echolocation, relevant problem-solving generalization, chemical recognition (olfaction), mimicry, scene analysis, chemical synthesis—evolved adaptations are at least as good as and usually strikingly better than human engineered systems, in those rare situations in which humans can build systems that can accomplish them at all. It seems reasonable to insist that before a system is criticized as being poorly designed, the critic ought to be able to construct a better alternative—a requirement, it need hardly be pointed out, that has never been met by anyone who has argued that adaptations are poorly designed. Thus, although adaptations are certainly suboptimal in some ultimate sense, it is an empirically demonstrable fact that the short-run constraints on selective optimization do not prevent the emergence of superlatively organized computational adaptations in brains. Indeed, aside from the exotic nature of the problems that the brain was designed to solve, it is exactly this sheer functional intricacy that makes our architecture so difficult to reverse-engineer and to understand.

Cognitive adaptations reflect the structure of the adaptive problem and the ancestral world

Four lessons emerge from the study of natural competences, such as vision and language: (1) most adaptive information-processing problems are complex; (2) the evolved solution to these problems is usually machinery that is well engineered for the task; (3) this machinery is usually specialized to fit the particular nature of the problem; and (4) its evolved design often embodies substantial and contentful “innate knowledge” about problem-relevant aspects of the world.

Well-studied adaptations overwhelmingly achieve their functional outcomes because they display an intricately engineered coordination between their specialized design features and the detailed structure of the task and task environment. Like a code that has been torn in two and given to separate couriers, the two halves (the structure of the mechanism and the structure of the task) must be put together to be understood. To function,

adaptations evolve such that their causal properties rely on and exploit these stable and enduring statistical and structural regularities in the world. Thus, to map the structures of our cognitive devices, we need to understand the structures of the problems that they solve, and the problem-relevant parts of the hunter-gatherer world. If studying face recognition mechanisms, one must study the recurrent structure of faces. If studying social cognition, one must study the recurrent structure of hunter-gatherer social life. For vision, the problems are not so very different for a modern scientist and a Pleistocene hunter-gatherer, so the folk notions of function that perception researchers use are not a problem. But the more one strays from low-level perception, the more one needs to know about human behavioral ecology and the structure of the ancestral world.

Experimenting with ancestrally valid tasks and stimuli

Although bringing cognitive neuroscience current with modern evolutionary biology offers many new research tools (Preuss, 1995; see also chapter 84), we have out of necessity limited discussion to only one: an evolutionary functionalist research strategy (see chapter 87 and Tooby and Cosmides, 1992, for a description; for examples, see chapters in Barkow et al., 1992; Daly and Wilson, 1995; Gaulin, 1995; and chapter 81). The adoption of such an approach will modify research practice in many ways. Perhaps most significantly, researchers will no longer have to operate purely by intuition or guesswork to know which kinds of tasks and stimuli to expose subjects to. Using knowledge from evolutionary biology, behavioral ecology, animal behavior, and hunter-gatherer studies, they can construct ancestrally or adaptively valid stimuli and tasks. These are stimuli that would have had adaptive significance in ancestral environments, and tasks that resemble (at least in some ways) the adaptive problems that our ancestors would have been selected to be able to solve.

The present widespread practice of using arbitrary stimuli of no adaptive significance (e.g., lists of random words, colored geometric shapes) or abstract experimental tasks of unknown relevance to Pleistocene life has sharply limited what researchers have observed and can observe about our evolved computational devices. This is because the adaptive specializations that are expected to constitute the majority of our neural architecture are designed to remain dormant until triggered by cues of the adaptively significant situations that they were designed to handle. The Wundtian and British Empiricist methodological assumption that complex stimuli, behaviors, representations, and compe-

tences are compounded out of simple ones has been empirically falsified in scores of cases (see, e.g., Gallistel, 1990), and so, restricting experimentation to such stimuli and tasks simply restricts what researchers can find to a highly impoverished and unrepresentative set of phenomena. In contrast, experimenters who use more biologically meaningful stimuli have had far better luck, as the collapse of behaviorism and its replacement by modern behavioral ecology have shown in the study of animal behavior. To take one example of its applicability to humans, effective mechanisms for Bayesian inference—undetected by 20 years of previous research using “modern” tasks and data formats—were activated by exposing subjects to information formatted in a way that hunter-gatherers would have encountered it (Brase et al., 1998; Cosmides and Tooby, 1996; Gigerenzer and Hoffrage, 1995). Equally, when subjects were given ancestrally valid social inference tasks (cheater detection, threat interpretation), previously unobserved adaptive reasoning specializations were activated, guiding subjects to act in accordance with evolutionarily predicted but otherwise odd patterns (Cosmides, 1989; Cosmides and Tooby, 1992; see also chapter 87).

Everyone accepts that one cannot study human language specializations by exposing subjects to meaningless sounds: the acoustic stimuli must contain the subtle, precise, high-level relationships that make sound language. Similarly, to move on to the study of other complex cognitive devices, subjects should be exposed to stimuli that contain the subtle, ancestrally valid relationships relevant to the diverse functions of these devices. In such an expanded research program, experimental stimuli and tasks would involve constituents such as faces, smiles, disgust expressions, foods, the depiction of socially significant situations, sexual attractiveness, habitat quality cues, animals, navigational problems, cues of kinship, rage displays, cues of contagion, motivational cues, distressed children, species-typical “body language,” rigid object mechanics, plants, predators, and other functional elements that would have been part of ancestral hunter-gatherer life. Investigations would look for functional subsystems that not only deal with such low-level and broadly functional competences as perception, attention, memory, and motor control, but also with higher-level ancestrally valid competences as well—mechanisms such as eye direction detectors (Baron-Cohen, 1994), face recognizers (e.g. Johnson and Morton, 1991), food memory subsystems (e.g., Hart et al., 1985; Caramazza and Shelton, 1998), person-specific memory, child care motivators (Daly and Wilson, 1995), and sexual jealousy modules.

Although these proposals to look for scores of content-sensitive circuits and domain-specific specializations will strike many as bizarre and even preposterous, they are well grounded in modern biology. We believe that in a decade or so they will look tame. If cognitive neuroscience is anything like investigations in domain-specific cognitive psychology (Hirschfeld and Gelman, 1994) and in modern animal behavior, researchers will be rewarded with the materialization of a rich array of functionally patterned phenomena that have not been observed so far because the mechanisms were never activated in the laboratory by exposure to ecologically appropriate stimuli. Although presently, the functions of most brain structures are largely unknown, pursuing such research directions may begin to populate the empty regions of our maps of the brain with circuit diagrams of discrete, functionally intelligible computational devices.

In short, because theories and principled systems of knowledge can function as organs of perception, the incorporation of a modern evolutionary framework into cognitive neuroscience may allow the community to detect ordered relationships in phenomena that otherwise seem too complex to be understood.

Conclusion

The aforementioned points indicate why cognitive neuroscience is pivotal to the progress of the brain sciences. There are an astronomical number of physical interactions and relationships in the brain, and blind empiricism rapidly drowns itself among the deluge of manic and enigmatic measurements. Through blind empiricism, one can equally drown at the cognitive level in a sea of irrelevant things that our computational devices can generate, from writing theology or dancing the mazurka to calling for the restoration of the Plantagenets to the throne of France. However, evolutionary biology, behavioral ecology, and hunter-gatherer studies can be used to identify and supply descriptions of the recurrent adaptive problems humans faced during their evolution. Supplemented with this knowledge, cognitive research techniques can abstract out of the welter of human cognitive performance a series of maps of the functional information-processing relationships that constitute our computational devices and that evolved to solve this particular set of problems: our cognitive architecture. These computational maps can then help us abstract out of the ocean of physical relationships in the brain that exact and minute subset that implements those information-processing relationships, because it is only these relationships that explain the existence and functional organization of the system. The immense number of

other physical relationships in the brain are incidental by-products of those narrow aspects that implement the functional computational architecture. Consequently, an adaptationist inventory and functional mapping of our cognitive devices can provide the essential theoretical guidance for neuroscientists that will allow them to home in on these narrow but meaningful aspects of neural organization, and to distinguish them from the sea of irrelevant neural phenomena.

NOTE

1. The genes underlying complex adaptations cannot vary substantially between individuals because if they did, the obligatory genetic shuffling that takes place during sexual reproduction would break apart the complex adaptations that had existed in the parents when these are recombined in the offspring generation. All the genetic subcomponents necessary to build the complex adaptation rarely would reappear together in the same individual if they were not being supplied reliably by both parents in all matings (for a discussion of the genetics of sexual recombination, species-typical adaptive design, and individual differences, see Tooby, 1982; Tooby and Cosmides, 1990b).

81 The Replacement of General-Purpose Learning Models with Adaptively Specialized Learning Modules

C. R. GALLISTEL

ABSTRACT Associative theories of learning assume a general-purpose learning process whose structure does not reflect the demands of a particular learning problem. By contrast, implicit in the studies of learning conducted by zoologists and, recently, by some experimental psychologists, is the assumption that learning mechanisms are specialized computationally for solving particular kinds of problems. Models of the latter kind have begun to be applied even to the results from experiments on classical and instrumental conditioning. These models imply that to understand learning neurobiologically, we must discover the cellular mechanisms by which the nervous system stores and retrieves the values of variables and carries out the elementary computational operations (the elementary operations of arithmetic and logic). At the systems level, we must discover the circuits that implement special-purpose computations using these universal elements of computation.

Theories of learning are and always have been predominantly associative theories. However, in the study of animal learning, where these theories historically have been most dominant, a different conception is gaining ground. Whereas associative theories have their historical roots in the empiricist philosophy of mind, the alternative conception has its roots in evolutionary biology, more particularly in zoology, that is, in the study of the natural history of animal behavior and of the mechanisms that enable animals to cope with the challenges posed by their habits of life.

Associative theories of learning assume a basic learning mechanism, or, in any event, a modest number of learning mechanisms. These mechanisms are distinguished by their properties—for example, whether they depend on temporal pairing—not by the particular kind of problem that their special structure enables them to solve. Indeed, people doing neural net modeling, which currently is the most widespread form of associative theorizing, often are at pains to point out that the network has solved a problem in the absence of an initial struc-

ture tailored to the solution of that problem (Becker and Hinton, 1992).

The alternative conceptualization, by contrast, takes for granted that biological mechanisms are hierarchically nested adaptive specializations, each mechanism constituting a particular solution to a particular problem. The foliated structure of the lung reflects its role as the organ of gas exchange, as does the specialized structure of the tissue that lines it. The structure of the hemoglobin molecule reflects its function as an oxygen carrier. The structure of the rhodopsin molecule reflects its function as a photon-activated enzyme. One cannot use a hemoglobin molecule as the first stage in light transduction and one cannot use a rhodopsin molecule as an oxygen carrier, any more than one can see with an ear or hear with an eye. Adaptive specialization of mechanism is so ubiquitous and so obvious in biology, at every level of analysis, and for every kind of function, that no one thinks it necessary to call attention to it as a general principle about biological mechanisms.

In this light, it is odd but true that most past and contemporary theorizing about learning does not assume that learning mechanisms are adaptively specialized for the solution of particular kinds of problems. Most theorizing assumes that there is a general-purpose learning process in the brain, a process adapted only to solving the problem of learning. There is no attempt to formalize what the problem of learning is and thereby determine whether it can in fact be conceived of as a single or uniform problem. From a biological perspective, this assumption is equivalent to assuming that there is a general-purpose sensory organ that solves the problem of sensing.

In this chapter, I review some of the evidence that whenever learning occurs, it is made possible by an adaptively specialized learning mechanism—a learning module—whose structure is as specific to a particular learning problem as the structure of a sensory organ like the eye or the ear is specific to a particular stimulus

modality. Gould and Marler (1987) call these modules “learning instincts,” emphasizing that they have the same problem-specific structure that we see in instinctive behaviors. The review focuses on the differences in computational structure between several distinct learning mechanisms that are important to an animal’s ability to find its way about and a different set of mechanisms that enable it to learn and exploit the temporal structure of its experience. I finish with some observations on the implications of this view for research on the neural mechanisms of learning and memory.

Rozin and Kalat (1971) were among the first to argue for adaptive specializations of learning from a biological natural-history perspective, and Chomsky (1975) was among the first to argue for it on computational grounds. Early work focusing on the role of adaptive specialization in learning tended to formulate the problem in terms of the constraints (Hinde and Hinde, 1973) or boundaries (Seligman and Hager, 1972) that biological considerations placed on *the* learning process. By contrast, the argument advanced by Chomsky (1975), Gould and Marler (1987), Gelman and Williams (1998), and Gallistel (1990) is that there is no such thing as *the* learning process; rather, there are many different learning processes. While it is true that the structure of these processes constrain the outcome of learning in interesting ways, the more important point is that it is the problem-specific structure of these processes that makes learning possible.

Spatial learning mechanisms

LEARNING BY PATH INTEGRATION Our first example of a learning module is so far removed from what commonly is regarded as a learning mechanism that before I discuss it, I usually get people to agree that the pretheoretic definition of a learning mechanism is a mechanism by which we acquire knowledge of the world and our place in it. Then, I show them figure 81.1, which is the track of a long-legged fast-moving desert ant, *Cataglyphis bicolor*, foraging for and finding a morsel of food on the hot plain of the Tunisian desert. On the outward leg of its journey (solid tracing), the ant twists and turns this way and that searching for the carcass of an insect that has succumbed to the heat. When it finally finds one, it bites off a chunk, turns, and runs more or less straight toward its nest, a hole 1 mm in diameter, which may be as far as 50 m away. Its ability to orient homeward demonstrably depends on information it acquires during the outward journey. If the ant is deprived of this information by being picked up as it emerges from the nest and transported to an arbitrary point in the vicinity of its nest, it wanders in circles and

FIGURE 81.1 Track of a foraging ant. The outward (searching) journey is the solid line. It found food at X. Its homeward run is the broken line. (Redrawn from Harkness and Maroudas, 1985. Used with permission of the author and publisher.)

FIGURE 81.2 The homeward run of an ant displaced into unfamiliar territory on which the experimenters had previously marked off a 1-m gridwork. *S* indicates the point of release. *N** indicates the location of the fictive nest (where the ant’s nest would have been had the ant not been displaced). *O* indicates the point at which the ant terminated its nestward run and entered a search pattern. (Redrawn from Wehner and Srinivasan, 1981. Used with permission of the author and publisher.)

makes it back to the nest only after a long time, if at all (Wehner and Flatt, 1972). A simple experiment by Wehner and Srinivasan (1981) reveals the nature of the learning mechanism that acquires the requisite position information. When the ant turns from a food source back toward its nest, it is picked up and transported more than half a kilometer across the desert; here it is released to run across a large grid the experimenter has marked in advance on the desert floor. The grid on the desert enables the experimenter to trace the ant’s course on a graph-paper grid at a reduction of 100:1 (figure 81.2). Although the ant is now in territory it has never seen, it runs in a direction that lies within a degree or two of the compass direction of its nest from the site where it was picked up, the direction in which it would have run had it not been displaced. It runs in a straight line for a distance slightly longer than the distance of its nest from the point where it was picked up, then stops

abruptly its straight run to begin a systematic search for the nonexistent nest.

The ant's ability to run over unfamiliar terrain a course whose direction and distance equal the direction and distance of its nest from the point of its capture implies that its navigation is based on some form of path integration or dead reckoning. Path integration is the integration of the velocity vector with respect to time to obtain the position vector, or a discrete approximation to this computation. The discrete approximation in traditional marine navigation is to record the direction and speed of travel (the velocity) at intervals, multiply each recorded velocity by the interval since the previous recording to get interval-by-interval displacements (e.g., making 5 knots on a northeast course for half an hour puts the ship 2.5 nautical miles northeast of where it was), and sum the successive displacements (changes in position) to get the net change in position. These running sums of the longitudinal and latitudinal displacements are the deduced reckoning of the ship's location (abbreviated "ded. reckoning," thus, "dead reckoning").

For this computation to be possible, the ant's nervous system must have elements capable of preserving the value of a variable over time. The essence of the ongoing summation that underlies path integration is the adding of values that specify the most recent displacement to the values that specify the cumulative prior displacement. To do this, one must be able to hold in memory the value of the sum, and add to that value.

Path integration is a process that computes and stores values that specify a quantifiable objective fact about the world—the ant's direction and distance from its nest. The use made of the values, if any, is determined by the decision process-controlling behavior at the moment. The integration of velocity to obtain position goes on throughout the ant's journey, but only when the decision to turn for home is made do the position coordinates stored in the dead-reckoning integrator lead to the well-oriented straight runs for a predetermined distance shown in figures 81.1 and 81.2. The position-specifying values (coordinates) in the nervous system are in no sense associative bonds: they were not created by temporal pairing and they do not function as conducting links in the circuitry that links sensory input to behavioral output, nor in circuitry that links the memory of one sensory input to the memory of a different sensory input. Rather, these coordinates are symbols. Their values (magnitudes) specify a fact about the world, which different decision processes may use in different ways. They are no more conducting links than are memory locations in a computer or genes on a chromosome. Like these two examples, they are repositories of information.

The values accumulated in the integrator at important points in the forager's journey may also be stored for later use—either in the direction of overt behavior or in computations that lead to the storing of other facts about the world. For example, the ant stores the coordinates of the location at which it finds the carcass, so that it can return directly there on its next foraging trip. We infer this because when we set up a food source in a fixed location, the ants soon come directly to it from their nest (Wehner and Srinivasan, 1981). These fast-moving ants do not lay an odor trail, so their ability to set a course directly for the food source from the nest implies that they have recorded its position relative to the nest.

The foraging bee gives direct evidence that it has stored the coordinates of a food source for later use. When it returns to its hive, it performs a symbolic dance. It runs in a figure-eight path, wagging when it runs the central segment where the two loops join. Other foragers follow behind the dancing bee to learn the location of the food source. The direction of the wagging part of the run relative to the gravitational vertical specifies the direction of the food source relative to the sun (the solar bearing of the source), whereas the number of waggles specifies the approximate distance of the source from the hive (Frisch, 1967). In this way, the bee communicates to others the position-specifying values computed and saved by its path-integrating mechanism. This is but one of several possible illustrations of the diverse uses to which values stored in memory may be put by different behavioral read-out systems.

If the adaptive specialization of the complex computations that mediate information acquisition is taken for granted, the only plausible elementary mechanisms that might be common to learning mechanisms in general are a mechanism for storing and retrieving the computed values of variables and the mechanisms that carry out the primitive elements of all computation (adding, subtracting, multiplying, dividing, ordination, conditional testing, and so on). Path integration is a notably simple and widespread neural computation that makes straightforward use of these elementary computational operations. It should, therefore, be of central interest to the large community of scientists who seek to discover the cellular-level mechanisms that make learning and higher cognitive function possible. In other words, it should be regarded as a paradigmatic learning process worthy of intensive study at the neurobiological level.

Why then do many people find the idea of path integration as a paradigmatic and notably simple instance of learning perverse? The reasons offered are revelatory. First, it is argued that it is a special-purpose innate mechanism designed to do this and only this. In short, it is an adaptive specialization. This is equivalent to arguing that

the eye is not a representative example of a sensory organ because it is designed specifically for vision. The argument presupposes that there is such a thing as a general-purpose learning mechanism, which is the presupposition that the zoological approach to learning calls into question.

Another reason offered for regarding path integration as unusual is that the ant does not have to experience its outward journey repeatedly before it knows the way. A variant of this argument is that the ant does not get better at running home with repeated practice. These objections reify the basic assumption of associative theory, which is that learning involves the gradual strengthening of something. To be sure, the conditioned response in classical conditioning usually does not appear until there have been several co-occurrences of the conditioned and unconditioned stimuli, but the only apparent justification for making strengthening through repetition part of the definition of learning is the conviction that there is a general purpose learning mechanism and that the classical conditioning paradigm captures its essence. If we think that path integration captures the only essence of learning that is there to be captured, then we are not going to make strengthening by repetition part of the definition of learning. Moreover, as will be shown later in the chapter, the domain-specific approach to learning mechanisms offers an interpretation of classical conditioning in which the notion of strengthening a conductive connection through repeated pairing of stimuli plays no role.

LEARNING THE SOLAR EPHEMERIS Dead reckoning requires a fixed directional reference; the animal must know which way is north at all times. A wide variety of animals, including the ant, derive this information from the sun's azimuth, the point on the horizon above which the sun is positioned at a given moment. This is remarkable because to use the sun for directional reference, the animal must know the solar ephemeris, the sun's position as a function of the time of the year and the day. Because the sun's azimuth at a given time of day depends strongly on the animal's latitude and the time of year, the solar ephemeris must be learned. A recent experiment by Dyer and Dickinson (1994) sheds new light on the mechanism that is specialized to learn this.

It has long been known that one of the characteristics of the mechanism that learns the solar ephemeris is that it enables animals to judge the position of the sun at times of day when they have never seen—and will never see—the sun. Honeybees at mid-northern latitudes, for example, treat a sun substitute presented at midnight on their internal clock as if it were due north (Lindauer, 1957). Bees that have only experienced the sun in the af-

ternoon, when it is in the west, assume that it is nonetheless in the east in the morning (Lindauer, 1959). The most common explanation of this has been that bees learn the average angular velocity of the sun's azimuth (the number of degrees it moves along the horizon per hour) and extrapolate its position by multiplying its average velocity by the time elapsed since they last saw it. This explanation always has been somewhat problematic because at tropical latitudes, the sun's angular velocity is negligible throughout the late afternoon, and bees evolved in the tropics.

In any event, the Dyer and Dickinson experiments show that it is not extrapolation but rather curve fitting that enables the bees to know the sun's direction at times of day when they have never observed it. Dyer and Dickinson restricted the foraging experience of incubator-raised bees to the last 4 hours of daylight, during which the sun always was more or less in the west, with its azimuth moving through less than 20% of the angle it covers between dawn and dusk. The bees foraged from a single source due south of the hive. As already noted, the dance that the bees execute when they return to the hive indicates the solar bearing of the source. When the source is due south of the hive (compass bearing 180°) and the sun due west (compass bearing 270°), then the dance is at an angle of $180^\circ - 270^\circ = -90^\circ$, or 90° to the left of vertical, the number of degrees that the source is counterclockwise from the current position of the sun. When the compass bearing of the source is fixed, the angle of the dance is the bee's estimate of the sun's azimuth.

On heavily overcast days, when bees cannot see the direction of the sun (Brines and Gould, 1982), returning foragers dance nonetheless. They can do so because they have learned the solar ephemeris. They know where the sun is when they cannot see it. In the early morning of such a day, Dyer and Dickinson released the bees that had seen the sun only in the afternoon. The released bees foraged from the fixed source throughout the day, and the changing angle of their dance indicated their changing estimate of where the sun was—the solar ephemeris that they had derived from their limited experience of the sun's movement. The results are in figure 81.3.

As in Lindauer's classic experiments, bees that had never experienced the sun except in the afternoon, when it is in the west, nonetheless believed it to be (or acted as though it were) in the east in the morning. But, as the morning wore on, they did not think that it moved steadily into the south, as they would if they extrapolated the previously observed motion of the sun in any of the ways that have been proposed previously (dashed lines in figure 81.3). In the solar ephemeris that

these bees had derived from their limited experience, the sun stayed in the east until about noon, when it moved abruptly into the west, changing its azimuth by 180° in a very short time. In short, the mechanism for learning the solar ephemeris has built into it what is universally true about the sun, no matter where one is on the earth: it is somewhere in the east in the morning and somewhere in the west in the afternoon. Learning the solar ephemeris simply is a matter of adjusting the parameters of this universal ephemeris function to make it fit the locally observed motion of the sun.

This learning mechanism is reminiscent of the mechanism by which birds learn to sing a song appropriate to their species and region (Marler, 1991), despite the fact that they hear songs from many other species, some closely related, during the period when they are learning their own song. Built into the song-learning mechanism is a template or selective filter, which enables the birds to recognize the kind of song that they should be learning, the features that are universal in the song of that species. The ephemeris-learning mechanism also is reminiscent of contemporary theories of language learning, which assume that the learning of a human language is a matter of establishing through observation the parameter values that enable a universal grammar to generate the language spoken locally (Chomsky, 1981; Roeper and Williams, 1987). The universal grammar has built

into it what is universally true about human languages just as the solar ephemeris mechanism has built into it what is universally true about the sun's motion.

If problem-specific learning mechanisms are required to explain everything from the learning of the solar ephemeris in bees to song learning in birds and language learning in humans, should we nonetheless continue to imagine that there exists a general-purpose learning mechanism in addition to all these problem-specific learning mechanisms? What structure could it have? It is like trying to imagine the structure of a general-purpose organ, the organ that takes care of the problems not taken care of by adaptively specialized organs like the liver, the kidney, the heart, and the lungs.

Temporal learning mechanisms

Although there are no current proposals for a general-purpose organ, there is a centuries-old and still very popular proposal for a general-purpose learning mechanism—the mechanism of association formation. An association is a connection between two units of mental or neural activity (two ideas, two neurons, two nodes in a neural net, etc.). The associative connection arises either because the two units often have been active at nearly the same time (the temporal pairing of activation) or through the repeated operation of a feedback mechanism that is activated by errors in the output and adjusts associative strengths to reduce the error. In traditional animal learning theory, the process that forms associations by the first mechanism (temporal pairing of activation) is called the classical or Pavlovian conditioning process, whereas the process that forms associations through the agency of error-correcting feedback is called the instrumental or operant conditioning process. In neural net modeling, the first process is called an unsupervised learning mechanism (Becker and Hinton, 1992) in contrast to the more common second mechanism, which requires a supervisor or teacher who knows the correct output. The correct output is required for the error-actuated back-propagation algorithm, which selectively strengthens connections that lead to correct outputs and weakens those that do not. In theories of instrumental learning (Hull, 1943), the error-correcting feedback comes from the rewards and punishments generated by effective acts.

The Pavlovian and instrumental or operant experimental paradigms were created to study the principles of association formation. The creators shared with contemporary connectionist modelers the assumption that the general nature of learning already was known; it was associative. The problem was to determine the details of the associative process and how it explained whatever it

FIGURE 81.3 The solar azimuth indicated by the dances of returning foragers (+) as a function of the time of day. The bees could not see the sun. The foraging site was due south of the hive. The gray zone indicates the period during which the bees had been allowed to forage with a view of the sun on previous days. The solid curve is the actual solar azimuth. The numbered dashed lines indicate the sun's azimuth as extrapolated in various imaginable ways from the motion observed during the gray period. was that subjects were observed to learn. Conditioning paradigms were not intended to be laboratory analogs of particular learning problems that animals had been observed to solve in the field. This does not mean, of course, that the paradigms do not in fact represent problems of a particular kind. In fact they do. From a mathematical perspective, they are examples of problems in *multivariate, nonstationary time-series* analysis.

They are *time-series* problems because what the animals are learning is the temporal dependence of one event on another, that is, temporal *contingency*. One of the most important discoveries to emerge from the modern study of conditioning is that temporal pairing is neither necessary nor sufficient for conditioning because it is contingency, not temporal pairing, that drives conditioning.

Contingency cannot be reduced to temporal pairing. Imagine, for example, an experimental protocol in which the opening of the grain hopper (the US) occurs only when a key on the wall of a pigeon's cage (the CS) is illuminated. (This is the standard classical conditioning protocol.) The opening of the hopper is contingent on the illumination of the key. The contingency is just as great if the hopper only opens when the key is not illuminated, never when it is illuminated. (This is called the explicitly unpaired protocol.) Both contingencies are learned equally readily (Colwill, 1991; Kaplan, 1984; LoLordo and Fairless, 1985; Rescorla, 1969), yet in the second, the CS and US are never paired (the hopper opens only when the key is not illuminated), whereas in the first, they always are paired (the hopper opens only when the key is illuminated). The fact that animals learn negative contingencies as readily as positive contingencies establishes that temporal pairing is not necessary for conditioning.

Conditioning protocols are *multivariate* time-series problems because there are many different events or time-varying conditions that may or may not predict the time or rate of US occurrence. An important challenge that the animal faces is figuring out what predicts what. This is the multivariate problem. The modern era in the study of conditioning began with the almost simultaneous discovery by three different laboratories of the fact that the learning mechanism operating during conditioning experiments solves the multivariate problem in ingenious and sophisticated ways (Kamin, 1969; Rescorla, 1968; Wagner et al., 1968). For example, imagine a rat that already has learned that the onset of noise predicts shock. If we give trials in which noise and light come on together, followed by shock, the rat does not learn that the onset of the light predicts shock—no matter how often the light and the shock are paired. This is called blocking. Intuitively, the light does not predict

anything new, anything that is not predicted already by the noise. The discovery of blocking and closely related phenomena (overshadowing, the effects of background conditioning, and the effects of the relative validity of the CSs) showed that temporal pairing is not sufficient for conditioning. Thus, conditioning by negative contingency and blocking between them establish the fundamental point that conditioning is not mediated by temporal pairing.

Conditioning protocols require solutions to the problem of *nonstationarity*, because the contingencies between CSs and USs commonly change from one phase of the experiment to another. In extinction experiments, for example, the rate of reinforcement (US delivery) is higher when the CS is present, but only during the training phase of the experiment. During a subsequent extinction phase, the rate of reinforcement is zero when the CS is present. This is an example of a nonstationary temporal dependency, a contingency that itself changes over time. It has been known since the early days of the study of both classical and operant conditioning that subjects detect these changes in contingency and alter their behavior appropriately. They cease responding to the CS during the extinction phase and resume responding to it if the extinction phase is followed by a reacquisition phase. The possibility that the contingency itself may change over time requires a particularly sophisticated kind of time-series analysis, one that detects and takes into account nonstationarity.

The fact that conditioning protocols present problems in multivariate, nonstationary time-series analysis is irrelevant from the perspective of associative models of the conditioning process because the associative process is not assumed to be specialized for this or any other particular sort of problem. For that very reason, it has proved difficult to elaborate a real-time¹ associative model of the conditioning process capable of explaining in an internally consistent, mathematically simple, and economical way the results from conditioning experiments (Gallistel and Gibbon, in press). In recent years, models that take as their point of departure the assumption that the results are generated by a learning mechanism specifically tailored to solve this kind of problem have been more successful (Gallistel and Gibbon, in press). They naturally explain fundamental features of the conditioning data that have challenged associative models for decades.

The problems that associative models confront in attempting to explain the results of classical and operant conditioning experiments are numerous (Gallistel and Gibbon, in press), but many of them stem from the *time-scale invariance* of the conditioning process. This means that when one conducts the same experiment at differ-

FIGURE 81.4 Dew's (1970) data on the normalized rate of responding during the inter-reward interval on fixed interval schedules ranging from 30 s to 3,000 s, as a function of the normalized time in the interval. The normalized rate is the average rate at elapsed time, t , since the most recent reward divided by the average rate at latency, T , just before the next reward. The normalized time is t/T . The responding in any one inter-reward interval is discontinuous. The seemingly smooth acceleration of responding seen here is an averaging artifact. These data show that the distribution of response onsets is time-scale invariant because the normalized distributions superimpose. (Reproduced with minor modifications from Gibbon, 1977, and used by permission of the author and publisher.)

ent scales—multiplying or dividing all the time intervals in the protocol by a common factor—one gets the same results. The results do not vary when the time scale of the experiment is varied by as much as one or even two orders of magnitude.

The simplest example of the time-scale invariance of conditioned behavior—and the first to be noted (Dews, 1970; Gibbon, 1972; Gibbon, 1977)—is in the timing of the operant (instrumental) response. If, as is commonly the case, the animal's response can elicit a reinforcement only after a fixed interval has elapsed since the onset of a conditioned stimulus or since the last reinforcement (e.g., on a fixed interval [FI] schedule), then the conditioned response (key pecking or lever pressing) begins on average at some fixed proportion of the reinforcement latency (the interval that must elapse before reinforcement can be obtained). Because the ratio between the reinforcement latency and the onset of responding is constant, the time scale for the experimental protocol does not matter. The moment at which responding begins varies substantially from one inter-reinforcement interval to the next (or from one CS presentation to the next), but this variability also is proportional to reinforcement latency. Thus, when the distributions of response onsets (and offsets) are normal-

ized, that is, when the time scale is taken out, they are superimposable (figure 81.4). Thus, the noise or variability in the timing of the conditioned response is time-scale invariant (Gibbon, 1977; Gibbon, Church, and Meck, 1984).

Explaining the fact that the timing of the onsets and offsets of conditioned responding is proportional to reinforcement latency is one of the challenges that associative models of the conditioning process have not confronted. It implies that the subjects remember the reinforcement latency and base their behavior on a comparison between this remembered interval and a currently elapsing interval. Because associative bonds are assumed to be conducting links whose current strengths depend on many different aspects of the subject's conditioning experience, they cannot readily be made to specify (code for) reinforcement latency. Reinforcement latency (the delay of reinforcement) usually is assumed to be one of several variables that *determine* increments in associative strength, rather than a variable whose value is *encoded by* associative strength.²

The acquisition process in conditioning also is time-scale invariant. This means that changing the duration of the intervals in a conditioning protocol (e.g., the delay of reinforcement) has no effect on the rate of conditioning (the inverse of reinforcements to acquisition) provided one does not change the temporal proportions—how much of one kind of interval there is relative to each other kind. It is these proportions that determine the rate of conditioning, not the intervals themselves.

It is commonly but erroneously taken for granted that delaying reinforcement retards or prevents the acquisition of conditioned responding (Usherwood, 1993, p. 427). Experiments that seemed to show this (Coleman and Gormezano, 1971; Schneiderman and Gormezano, 1964) did not change the intertrial interval (the interval between CS-US pairings) in proportion to the changes in the delay between CS onset and the US (the delay or reinforcement). When the intertrial interval is increased in proportion to the increase in the delay of reinforcement, delay of reinforcement has no effect on the rate of acquisition (figure 81.5).

The time-scale invariance of the acquisition process also is manifest in the surprising fact that partial reinforcement does not affect either the rate of acquisition or the rate of extinction. During training, the number of reinforcements required for acquisition (hence, the rate of acquisition) is not affected by mixing in as many as nine unreinforced trials for every one reinforced trial (see the more or less flat dashed lines in figure 81.6B). When the subjects then are shifted to extinction (no reinforcements at all), the proportion of reinforced trials

FIGURE 81.5 Reinforcements to acquisition in the pigeon autoshaping paradigm as a function of delay of reinforcement, with intertrial interval (I) fixed and with intertrial interval varying in proportion to the delay (I/T fixed). Note that delay of reinforcement (T) appears to have a strong affect on reinforcements to acquisition (hence, on the rate of conditioning) if the intertrial interval is not varied. But when the intertrial interval, I , is varied in proportion to the variations in the delay of reinforcement, delay of reinforcement is seen to have no effect. (From Gallistel and Gibbon, in press.)

during training has no effect on how many reinforcements must be omitted to induce the subject to stop responding (see the more or less flat dashed lines in figure 81.6C). (The rate of extinction is the inverse of this number, the number of reinforcements that must be omitted to extinguish the conditioned response to the CS.)

The failure of partial reinforcement to affect the rates of acquisition and extinction is profoundly puzzling from an associative perspective. Because the effects of unreinforced trials are assumed to antagonize the effects of reinforced trials (to weaken net excitatory strength), intermingling unreinforced trials with the reinforced trials during acquisition should augment the number of reinforced trials required for acquisition. It also should make the net excitatory strength of the associative bonds after any given number of reinforced trials weaker, so that it takes fewer unreinforced trials to produce extinction. Neither result is in fact seen. This directly challenges the fundamental idea that reinforcement and nonreinforcement have opposing effects on the strengths of associative connections.

The lack of an effect of partial reinforcement is an example of time-scale invariance because partial reinforcement does not change the relative amounts of exposure to the CS and to the background per reinforcement, and it is these proportions that determine the rate of acquisition.

Consider, for example, the 1:1 schedule of reinforcement (one reinforcement at the termination of each illumination of the key) with the key illuminations (the “trials”) each lasting T seconds. After the reinforcement (the opportunity to eat from the food hopper), there is a period of I seconds during which the background alone (the experimental chamber) is present. At the end of this intertrial interval, the cycle repeats itself—key illumination for T seconds, reinforcement, intertrial interval for I seconds. Thus, in each cycle, the subject gets T seconds of exposure to the CS and I seconds of exposure to the background alone. Now consider the case when there is a 2:1 schedule of reinforcement (the food hopper opens at the termination of, on average, every second illumination of the key). Now the subject sees the CS on average twice before the hopper opens, for an average of $2T$ seconds of CS exposure per CS reinforcement. But it also experiences the background alone for, on average, $2I$ seconds between each reinforcement of the CS. Thus, the relative amounts of exposure to the CS and to the background alone are not affected by the reinforcement schedule. Because conditioning depends only on these unaltered temporal proportions (the principle of time-scale invariance), partial reinforcement affects neither the rate of acquisition nor the rate of subsequent extinction.

Explaining the time-scale invariance of conditioning is difficult for associative models for three interrelated reasons: (1) they usually assume that temporal pairing is important; (2) they invariably assume that it is differences in probability of reinforcement that are important; and (3) they commonly divide continuous time into discrete trials. Each of these assumptions would appear to make time-scale invariance impossible. The notion of temporal pairing assumes that there is some time window within which the CS and the US both must occur if they are to be regarded as temporally paired. The width of this window imposes a time scale on the process. Increasing the delay of reinforcement to the point at which the CS and the US are separated by more than the window of associability alters the outcome of the experiment (a violation of time-scale invariance). Probabilities of reinforcement and differences in probabilities of reinforcement cannot be defined except by assuming some discrete finite interval of time within which the probability is measured. That is, they cannot be defined without assuming that continuous time is divided into discrete trials, because the probability of any event goes to zero as the intervals within which probabilities are measured become arbitrarily small (and so do differences in probability). The values of all probabilities entering into an associative analysis depend on the assumed duration of the trials. Thus, the assumed trial duration imposes a time scale. The predictions of an as-

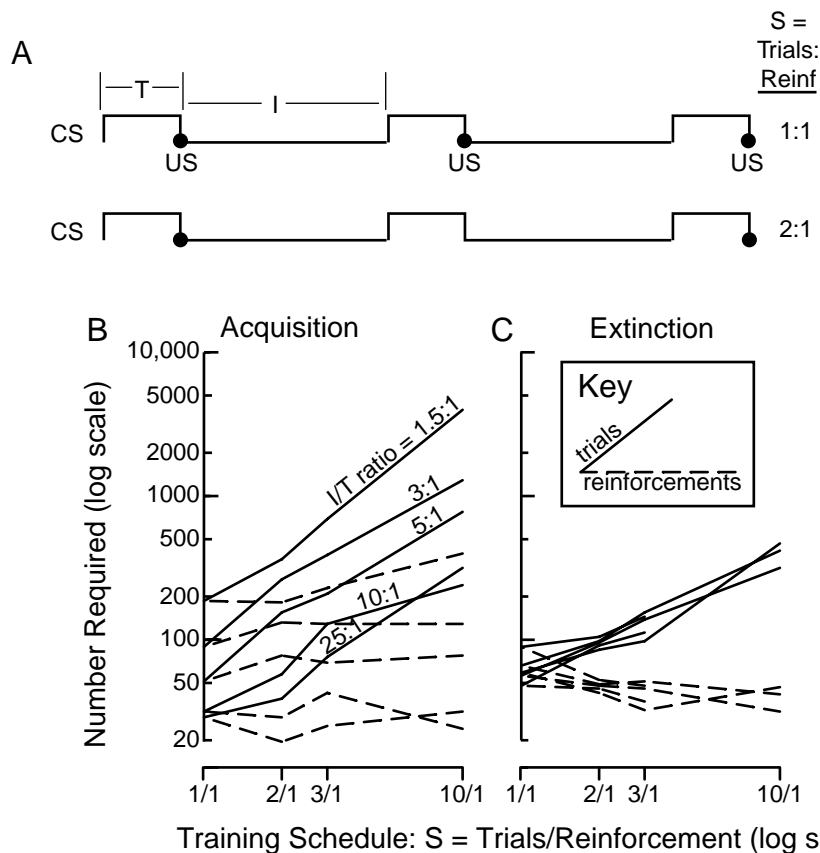

FIGURE 81.6 (A) The parameters of a simple conditioning protocol are T (the duration of a CS presentation, usually called a “trial”), I (the average interval between presentations, called the intertrial interval), and S , the reinforcement schedule (the ratio of trials to reinforcements). Dots indicate reinforcements, which are delivered at CS termination (on reinforced trials). Thus, T , the duration of each CS presentation also is the delay of reinforcement. (B) The effect of the partial reinforcement schedule (x axis) and the I/T ratio (between curves) on trials to acquisition (solid lines) and on reinforcements to acquisition (dashed lines). Note that partial reinforcement has no effect on reinforcements to acquisition (dashed lines), but

the I/T ratio has a dramatic effect: the greater the I/T ratio, the fewer reinforcements are required for acquisition. (C) The effect of the partial reinforcement schedule in force during training on unreinforced trials to extinction (solid lines) and on the number of omitted reinforcements to extinction (dashed lines). An omitted reinforcement is a reinforcement that would have been delivered by the training schedule, but was not. The rate of extinction is the reciprocal of the number of reinforcements that must be omitted to produce extinction; the higher this number, the slower the rate of extinction. (Reproduced from Gallistel and Gibbon, in press, by permission of author and publisher.)

sociative model (for fixed values of its parameters) change as the time scale of the experiment changes because events that fall within a single trial at one time scale fall in different trials on a different time scale.

Suppose, however, that we assume the following: (1) The mechanism that underlies conditioning is specialized to compute the effects of various stimulus conditions on the relative *rates* (N.B. not probabilities) of reinforcement. (2) It also is sensitive to the limits on the certainty with which these effects can be known given a limited amount of experience. That is, it is sensitive to the statistical uncertainties inherent in limited observations. These are the distinctive features of the problem that confronts animals in conditioning experiments. These also are the features of the problem that confronts

a foraging animal in the wild. If it is to forage efficiently, it must be sensitive to the differences in rates of reward at different sites and under different foraging conditions. It must detect changes in these rates, and it must be sensitive to the statistical uncertainties inherent in a limited number of observations. If it relies too much on the evidence from too small a sample, it constantly will be misled by chance fluctuations. If, to avoid being misled, it relies on the average from a large sample, it will be slow to adjust to genuine changes.

These considerations suggest that the operation of any mechanism well tuned to a problem with the structure of conditioning problems should be time-scale invariant because time series analysis itself is time-scale invariant. Changing time scales affects neither the relative rates of

reward, the limits on the certainty with which they can be known after a given number of reinforcements have been delivered, nor the number of interevent intervals that must be observed to detect a change in the rate of reinforcement. The simplest way to see that this must be so is to ask whether the units attached to the numbers going into a statistical analysis affect the outcome of that analysis.³ Of course they do not, because it is the proportions among the numbers (quantities) that determine the outcome of the analysis, not the units attached to them. Changing the units attached to the numbers (e.g., from seconds to days) is the same as changing the time scale of the experiment. Thus, a time-series analysis and any process that mimics such an analysis must be time-scale invariant.

In short, two assumptions that arise naturally in a perspective that takes for granted the functional specialization of learning mechanisms predict the time-scale invariance seen in the results from conditioning experiments. The first is that conditioning experiments test properties of the learning mechanism that enables animals to forage efficiently from a variety of sources with varying rates of reward. This is an assumption about the natural context for the behavior whose mechanism is examined in the laboratory. The second assumption is that the learning mechanism is specialized to deal with the computational challenges inherent in this kind of problem.

The aforementioned assumptions predict time-scale invariance in the sense of “lead one to expect.” It remains to elaborate a proposal for the computational structure of this learning mechanism that predicts in the sense of “generates,” which is what rate estimation theory does (Gallistel, 1990). In this model, the acquisition of conditioned responding in simple conditioning is based on the ratio between the subject’s estimate of the rate of reinforcement when the CS is present ($\hat{\lambda}_{cs}$) and its estimate of the rate of reinforcement when the background alone is present ($\hat{\lambda}_b$).

In a simple or basic conditioning protocol, there are no background reinforcements, that is, no reinforcements during the intertrial intervals. Because there are nST seconds of exposure to the CS per n reinforcements, the subject’s estimate of the rate of CS reinforcement, ($\hat{\lambda}_{cs}$) is $n/nST = 1/ST$ reinforcements per second, and this estimate does not change as n increases (i.e., as training goes on). But what about $\hat{\lambda}_b$, the subject’s estimate of the background rate of reinforcement? Because there are no reinforcements in the intertrial intervals, $\hat{\lambda}_b$ is assumed to be the reciprocal of the subject’s cumulative exposure to the background since the beginning of conditioning. For example, if the subject has experienced 1,000 seconds of unreinforced exposure to the chamber

alone, then its estimate of the possible rate of background reinforcement is 1/1,000. In making this estimate, which is the upper limit on what the rate of background reinforcement might be, given the animal’s experience so far, the learning module shows its sensitivity to the (objectively) important principle that “absence of evidence is not evidence of absence.” One thousand seconds of exposure to the chamber with no opening of the hopper except when the key was illuminated does not justify the conclusion that the hopper never opens when the key light is not on. It only justifies the conclusion that such events happen no more often than once in 1,000 seconds.

The estimate of the rate of CS reinforcement ($\hat{\lambda}_{cs}$) remains constant as conditioning goes on, but the longer that conditioning continues without background reinforcements, the smaller the $\hat{\lambda}_b$ becomes. Thus, the ratio $\hat{\lambda}_{cs}/\hat{\lambda}_b$ grows as conditioning continues. In rate estimation theory, this ratio, which is called the decision variable, grows in proportion to the number of reinforced trials. When it exceeds a threshold (the decision threshold), the animal begins to respond to the CS. Acquisition in this model is time-scale invariant because the decision variable, $\hat{\lambda}_{cs}/\hat{\lambda}_b$, is the ratio of two rates. This ratio is a dimensionless quantity.

Rate estimation theory explains acquisition without positing anything that is strengthened by reinforcement. It takes several co-occurrences of the CS and the US in simple conditioning before a conditioned response is seen because the conditioned response is a consequence of a decision process that is sensitive to the ambiguity inherent in a limited number of observations. Put another way, the process that leads to conditioned responding is designed to detect contingency, and contingency cannot be recognized unambiguously in the absence of several occurrences of the events in question. (If you happened to be brushing your teeth when the earthquake struck, your sense of civic responsibility should not lead you to give up dental hygiene.)

Rate estimation theory also predicts one of the best-established quantitative facts about the acquisition process (at least in pigeon autoshaping, which is the most widely used appetitive Pavlovian paradigm), namely that the rate of acquisition is directly proportional to the I/T ratio (figures 81.6 and 81.7). The I/T ratio is the amount of exposure to the background alone relative to the amount of exposure to the CS. The greater this ratio, the more uncommon it is for the CS to be present. Thus, what figure 81.7 shows is that when the CS is only rarely present, reinforcing it from time to time leads rapidly to conditioned behavior, whereas when the CS is present a large percentage of the time, reinforcing it leads only slowly to acquisition. Intuitively, the higher I/T ratio, the

FIGURE 81.7 Reinforcements to acquisition as a function of the I/T ratio (double logarithmic coordinates). The data are from the 12 experiments listed in the key. (Reproduced from figure 2 in Gibbon and Balsam, 1981, which see for citations listed in the key.)

more rapidly it becomes evident that the rate of background reinforcement must be significantly less than the rate of CS reinforcement. In the Gallistel and Gibbon model (in press), the I/T ratio is the constant of proportionality relating the number of reinforcements to the decision variable, $\hat{\lambda}_{CS} / \hat{\lambda}_b$. The higher this constant of proportionality, the sooner the decision variable reaches the decision threshold.

The rate estimates in rate estimation theory are generated by a mechanism that solves simple systems of linear equations by the usual process of matrix inversion. The functional structure of this module is determined entirely by (is a mathematical consequence of) two simple principles: (1) rate additivity: the estimated rates of reinforcement for each CS must sum to the rates observed when various combinations of CSs are present, and (2) predictor minimization (Occam's razor): when there is more than one additive solution, the solution that minimizes the sum of the absolute values of the predicted rates, and hence the number of predictor variables, is the preferred solution. This rate-estimating structure, whose problem-specific nature is obvious, predicts well-known effects of background conditioning, blocking, overshadowing, and relative va-

lidity (Gallistel, 1990). Unlike the predictions of associative models (Rescorla and Wagner, 1972), its predictions do not depend on parametric assumptions. They follow directly from the basic ideas in the model. The operation of the rate-estimating mechanism is time-scale invariant because the coefficients of the matrices that are inverted to obtain the rate estimates are ratios of temporal intervals in the protocol. Thus, they, too, are dimensionless quantities.

In Gallistel and Gibbon's (in press) model of the mechanism that mediates extinction, the decision variable is the ratio of the cumulative amount of exposure to the CS since the last reinforcement of the CS and the expected amount of CS exposure per CS reinforcement. This ratio gets greater in proportion to the number of unreinforced presentations of the CS because each such presentation augments the cumulative unreinforced exposure to the CS. When this ratio reaches a critical value—the decision threshold in extinction—the animal stops responding to the CS. This decision mechanism also is time-scale invariant because the decision variable is the ratio of two time intervals. The thinner the reinforcement schedule during training, the longer the expected amount of CS exposure per reinforcement, which is the denominator of the decision ratio. Hence, the amount of exposure to the CS during extinction—the numerator of the decision ratio—must be proportionately greater before the decision criterion is reached. This explains why the number of trials to extinction increases in proportion to the degree of partial reinforcement during training—the partial reinforcement extinction effect. The result is that the number of reinforcements that must be omitted to produce extinction—hence, the rate of extinction—is unaffected by partial reinforcement during training.

In this model of extinction, nothing gets weaker as extinction progresses. On the contrary, the decision variable grows as extinction progresses. It takes many unreinforced trials to produce extinction because changes in contingency, like contingency itself, cannot be recognized without extended experience. Before it can be concluded reliably that the contingency between the CS and the US has changed, the interval without a reinforcement must get much longer than the training experience has led the subject to expect. Note that once again, the mechanism that mediates this aspect of conditioning is tuned to the inherent structure of the problem to be solved.

In short, models that assume adaptively specialized rather than general-purpose learning mechanisms provide a systematic alternative to the general-purpose associative framework within which the results from Pavlovian and instrumental conditioning experiments traditionally have been understood. These models

explain in fundamentally different ways the basic phenomena of conditioning (e.g., the acquisition and extinction of the conditioned response). There is no notion of strengthening through repetition in these models. The associative bond is replaced by the concept of a decision variable whose magnitude depends on the ratio of two rate estimates.

Rate estimates are like the position coordinates generated by the dead-reckoning mechanism; they are symbolic quantities in the head, repositories of remembered information, not conducting links. They are computed from experience by a problem-specific learning module, a module adapted to the solution of multivariate, nonstationary time-series problems. The operation of this module is time-scale invariant because the problem that it solves is time-scale invariant.

The success of domain-specific modeling in the homeland of associative modeling suggests that learning mechanisms, like other biological mechanisms, invariably will exhibit adaptive specialization. We should no more expect to find a general-purpose learning mechanism than we should expect to find a general-purpose sensory organ.

The conclusion that learning is mediated by several different problem-specific modules, which compute symbolic representations of objectively specifiable properties of the animal's experience, has potentially profound consequences for neuroscience research. Temporal pairing does not appear to be relevant to the operation of any of these modules, including the modules that produce conditioned responses in Pavlovian and instrumental learning paradigms. Thus, efforts to find the cellular mechanism of learning based on the assumption that learning depends on temporal pairing may be searching for something that does not exist. For example, most of the interest in the cellular phenomena of long-term potentiation (LTP) and long-term depression (LTD) rests on the assumption that these mechanisms are the physical realization of changes in associative strength. If there is no such thing as an associative bond, then the significance of these cellular phenomena for neuroscience as a whole becomes problematic.

Despite long-standing and deeply entrenched views to the contrary, the brain no longer can be viewed as an amorphous plastic tissue that acquires its distinctive competencies from the environment acting on general purpose cellular-level learning mechanisms. Cognitive neuroscientists, as they trace out the functional circuitry of the brain, should be prepared to identify adaptive specializations as the most likely functional units they will find. At the circuit level, special-purpose circuitry is to be expected everywhere in the brain, just as it currently is expected routinely in the analysis of sensory

and motor function. At the cellular level, the only processes likely to be universal are the elementary computational processes for manipulating neural signals in accord with the laws of arithmetic and logic and for storing and retrieving the values of variables. Thus, an important question for neurobiology is how nervous tissue stores and retrieves the values of variables.

NOTES

1. That is, a model that does not require that experience be imagined to occur in discrete "trials." The trial assumption is ubiquitous in associative modeling. It makes most associative models unsuitable as models of possible cellular mechanisms of learning, because it has so far proved impossible to operationalize the notion of a trial, that is, to specify a priori (in the absence of a particular experimental protocol) what constitutes a learning trial. Thus, the division of the animal's experience into trials in associative modeling is ad hoc (not governed by explicit, generally applicable principles).
2. The size of an increment in associative strength is a function of more than one aspect of the events on a given trial. In most models, the increment in associative strength is, for example, a function of (at least) the intensity or magnitude of the unconditioned stimulus and the duration of the interval between the onset of the conditioned stimulus (CS) and the delivery of the US. It also is a function of the internal state of the animal—the pretrial strength of the association, and the pretrial strengths of other associations to the same US. In many models, it also is a function of the extent to which the animal is attending to the CS and/or the US. Therefore, the resulting strength of an associative connection confounds several properties of the animal's past experience—among them, the intensity of the USs, the duration of the CS-US interval, and the number and kind of trials the animal has experienced. Because of this confounding, none of these properties is recoverable from the current strength of the connections forged by the animal's cumulative conditioning experience. Put more formally, the strength of an associative connection is a many-one function of different properties of the conditioning protocol. Many-one functions are not invertible; you cannot get from the one back to the many. That is why the connection weights in a neural net generally do not specify specific facts about the system's experience, they merely cause the system to respond more adaptively to subsequent inputs. These altered connection weights cause the system to behave "as if" it knew something when in fact it does not, which is why these nets are called subsymbolic. The net does not know anything because it is impossible to recover from the weights of its connections any objective property of the inputs that the net has been given. Thus, there is no symbolic knowledge. Facts about the world are not represented therein.
3. Assuming, of course, that the units are used consistently, that is, that milliseconds (msec) are not used for some intervals and seconds (s) for others.

82 Social Control of Brains: From Behavior to Genes

RUSSELL D. FERNALD AND STEPHANIE A. WHITE

ABSTRACT It seems self-evident that the brain controls behavior, but can behavior also “control” the brain? Behavior can and does influence specific aspects of brain structure and function over three different time frames. A causal link is easy to establish on an evolutionary time scale because the selective forces of the ecological niche of the animal typically are reflected in body shape, sensory and motor systems, and behavior. Similarly, on a developmental time scale, behavior acts in concert with the environment to establish structural changes in the brain that influence an organism throughout its lifetime. Surprisingly, there currently is evidence that in real time, social behavior also causes changes in the brain in adult animals. These alterations, caused by behavioral interactions, often are related to reproductive behavior and can be dramatic and reversible. Understanding the mechanisms responsible for such dynamic changes in the nervous systems of adult animals is a major challenge. How does behavior sculpt the brain, and how are these changes controlled? In this chapter, the authors review some key examples of the kinds of changes caused over evolutionary and developmental time scales and describe more specifically how behavior influences cellular and molecular processes in the brain. Their studies link molecular events with organism behavior by using a model system in which social behaviors regulate reproduction. Understanding the mechanisms through which social encounters cause changes in the brain of organisms is a significant challenge that is likely to yield important insights about how the reality of one’s social world changes one’s physiology.

Among social animals, the behavior of one individual or group of individuals influences the behavior of others (Lorenz, 1935). The nature of this influence depends on the species, the situation, and the specific interaction. However, the most reliable predictor of the behavior and outcome of such encounters is the social status of the individuals involved. A dominant animal threatened by a nondominant animal behaves differently than does a dominant animal threatened by another dominant individual. Correspondingly, behavioral actions by a female produce very different reactions in males depending on their social status. Indeed, in every social system that has been observed, the behavior of individuals de-

pends in part on their social status and in part on their environment. For students of animal behavior, the fact that animals behave in a manner appropriate to their particular status provides an essential scientific framework for interpreting social behavior. But how does an animal recognize its status and then behave appropriately? How does it understand an opportunity to change its status upward or respond to an imposed change in status downward? Clearly, physiological and ultimately molecular processes must be matched with the external social status to allow the animal to act. Some of these physiological and molecular changes must precede behavioral change, but others are a consequence of that change. How are these controlled?

Von Uexküll (1909) first realized that every animal species experiences life differently, living in its own “Umwelt,” or unique perceptual world. A bat using sonic echoes to understand the world in darkness surely perceives its surroundings differently than does a giraffe that relies on its eyes, looking down on the scene from above, or a fish depending entirely on weak electrical signals for information. Each animal species has different sensory capabilities that, in turn, restrict the stimuli it can sense. This restriction on the perceived world necessarily constrains the possible behavioral responses of any animal. Writing at the turn of the century, von Uexküll could not possibly have anticipated the discovery of magnetic, electric, or pressure senses, nor could he have imagined vision that extends into the infrared and ultraviolet, or even that light detection exists at some remarkable places other than the eye (Arikawa, Suyama, and Fujii, 1996). These discoveries make his writing all the more prescient, and the many interesting, unusual “umwelts” discovered to date reveal the many ways that natural selection has shaped animal perceptions. These are matched by the variation in animal forms and functions, which also illustrate adaptations to the environment. Together, physiological and behavioral adaptations are quite spectacular, and with every discovery comes renewed surprise.

In thinking about evolutionary change, it is clear that the ultimate arbiter of successful adaptations is behavior.

RUSSELL D. FERNALD Neuroscience Program and Department of Psychology, Stanford University, Stanford, Calif.
STEPHANIE A. WHITE Neurosciences Program, Duke University, Durham, N.C.

An animal that survives does so because it behaves successfully during a multitude of interactions with other animals in its environment. However, behavior, in turn, depends on intricate physiological, cellular, and ultimately molecular adaptations. Thus, one major challenge in biology is to understand the linkage across these levels as an animal interacts with its world. How is behavior controlled by means of physiological processes, and, correspondingly, how does behavior influence physiological, cellular, or molecular events? In this review, we discuss examples of such synergistic interactions between behavior and physiology that occur at different biological time scales: evolutionary time, developmental time, and real time.

Natural selection for shape

An animal's habitat is the major selective force shaping resident animal's form and function. Some adaptations are so striking that one can guess where the animal lives simply by observing its appearance. A wonderful example is the star-nosed mole *Condylura cristata*. Moles have adapted to their subterranean, nocturnal existence by developing a specialized sensory organ on their snouts, known as Eimer's organ, which provides tactile information. The star-nosed mole, however, has the premier of snouts: A paired set of 11 fleshy appendages is assembled in a starfish-like array around its nostrils. The entire structure contains some 30,000 Eimer's organs. This packing density makes the star-nosed mole's snout arguably one of the most sensitive detection devices for tactile cues. What accounts for this flamboyance compared with the humble snout of the common eastern mole? The differences very likely reflect the different habitats each species lives in (Catania and Kass, 1995). The eastern mole negotiates a substratum of dry soil and rocks, whereas the star-nosed mole lives amidst muddier terrain. The softer soil of the star-nosed mole's underground "umwelt" was selected for its more delicate and elaborate sensory structure.

The brain of the star-nosed mole reflects its extreme sensory bias because the area devoted to vision is comparatively small compared with the area devoted to somatosensory perception. Electrical recordings from the somatosensory cortex reveal a large and precise topographic representation of the snout (Catania et al., 1993; Catania and Kaas, 1995). Cytochrome oxidase staining of the sensory area in each hemisphere produces 11 dark stripes of dense tissue separated by narrow regions of lesser staining, suggesting that each stripe conforms to one of the fleshy rays on the snout. These orderly maps of the mole's tactile world are thought to develop in a manner similar to the way that topographic maps form

in other sensory systems, namely through segregation of inputs that have temporally correlated activity. As the animal feels its way through its burrows, its vigorous behavior results in coactivation of neighboring regions on a single ray. This coactivation presumably leads to refinement of the map as correlated inputs are stabilized at the expense of uncorrelated ones. Although such patterning occurs before birth, as best illustrated in the visual system (Meister et al., 1991), initial patterns still are malleable postnatally and behavior can influence that refinement (e.g., Nudo et al., 1996). Such a mechanism is a primary example of how behavior, resulting in sensory stimulation, can shape brain structure.

The star-nosed mole exemplifies the intricate relationship among sensory capacity, biological structure, and behavior as molded by natural selection. The fleshy fingers on the snout advertise how habitat, in this case, a muddy substratum, molds biological form and function during evolution. As a result of its sensory adaptation, the animal has a specialized capacity to "feel" its environment. The most important feature of the "Umwelt" for this animal is clearly in the tactile domain requiring tactile-oriented behavior which, in turn, influences the synaptic connections in the somatosensory cortex of the mole's brain.

Natural selection in development

Adaptation on an evolutionary time-scale occurs over the course of generations. The first and most important requirement for this is reproduction. Successful reproduction requires exquisitely timed developmental and physiological changes coupled with relatively precise social interactions. Maturational adaptations are triggered by hormones, which are powerful molecules that sculpt physiological and morphological change to enable reproduction. Surviving to puberty, attracting mates, conceiving, bearing, and parenting progeny all depend on these changes. In most vertebrates, the earliest actions of hormones, known as organizational effects, occur close to birth, when our complement of sex chromosomes or some environmental cue such as temperature dictates which molecules shape our anatomy and physiology.

SEXUAL DIMORPHISM When Phoenix and colleagues (1959) first framed the organizational hypothesis of hormonal effects, their terminology was meant to convey the fact that the very circuitry of the nervous system was being shaped by the action of these molecules. The contrasting term "activational" hormonal effects referred to the waxing or waning of hormonal flow in response to proximate stimuli within a fully formed structure. Although this dichotomous categorization has proven to be a useful heuristic, accumulating evidence revealed

that hormones produce observable changes in neuronal structure both during development and in response to proximate stimuli.

A classic example of the extent to which hormones shape neural structure was the finding of Arnold, Nottebohm, and Pfaff (1976) that the size of key nuclei within the song circuit of songbirds was three to six times larger in males than in females. These size differences, visible in histological sections with the naked eye, are related to sex and seasonal differences in song behavior (but see also Brenowitz, Lent, and Kroodsma, 1995). To date, the list of sexual dimorphisms produced by hormonal effects is as diverse as our degree of knowledge about their significance. For example, in humans, there is a distinct difference in the shape of the splenium of the corpus callosum between men and women, although it is not known whether that morphological difference reflects a functional difference (deLacoste-Utamsing and Holloway, 1982; Holloway and deLacoste, 1986). In contrast, when differences in behaviors that are critical for the survival of the organism direct the research focus, it is easier to understand the relevance of the dimorphism.

This approach has been especially fruitful in studies on the electric fish, *Sternopygus* (reviewed in Zakon, 1996). In these visionless fish, electrical communication is used to detect and recognize conspecifics. Weak electric organ discharges (EODs) produced are sexually dimorphic such that adult females emit shorter duration pulses at higher frequencies than mature males. Androgen treatment lowers EOD frequency and duration, whereas estradiol 17 β and human chorionic gonadotropin raise it. The mechanism that underlies this dimorphic behavior has been identified at the molecular level. Within the electric organ, the presence of dihydrotestosterone slows the inactivation kinetics of the electrocyte sodium channel, and this is correlated with longer duration action potentials and lower frequency discharge (Ferrari, McAnelly, and Zakon, 1995). This hormonal modulation of channel kinetics is a novel finding that ultimately explains how a sexually dimorphic behavior is produced that allows these fish to recognize one another's gender.

NEURONAL PLASTICITY UNDERLYING MOTHER-INFANT INTERACTIONS During development, hormonal secretions sculpt differences not only between the sexes but also within each gender. Pervasive examples may be found during the formation of a social bond between parent and offspring in early life. Here, changes in the molecular and cellular properties of discrete neuronal populations reflect an interaction among diverse factors, including sensory stimulation, endocrine priming, neuronal plasticity, and behavior during development. Con-

sider the brief period when a young bird may have to learn what species it is and even the characteristics of a species-appropriate mate (Lorenz, 1935). Imprinting is the name given to the specialized, typically irreversible learning that occurs in early life resulting in a bond between mother and offspring or in mate choice often first observed years later. Stimuli appearing during a critical window of development acquire a potent valence for their influence on behavior. The surmise is that the sensitivity of the nervous system somehow is different during this critical period, heightening the impact of specific sensory cues on the cellular and molecular processes that underlie memory. The search for the biological basis for this brief learning process has produced a few candidates, but by and large, only the phenomenological features of these processes are well known (Lorenz, 1935).

Sensory systems play powerful roles in triggering hormonal flow and changes in adult stages of maturation as well. In pregnant sheep, the passage of the fetus through the birth canal provides cervicovaginal stimulation, triggering the release of oxytocin, a potent peptide for maternal behavior. For this to occur, the mother must be primed by the high levels of estrogen that are present during pregnancy. Simultaneously, the birthing sensation also changes the way that the mother perceives her lamb. Before birth, ewes are repelled by the odor of amniotic fluid and reject approaching lambs. Incredibly, after parturition, they find this same aroma attractive (Poindron, Levy, and Krehbiel, 1988) and lick and sniff the newborn, culminating in the formation of an enduring and highly selective bond between mother and lamb. The mechanistic basis for this phenomenon involves a change in the electrical activity of neurons in the olfactory bulb, where there are receptors for oxytocin. After birth, the number of mitral cells that respond to lamb odors increases (Kendrick, Levy, and Keverne, 1992), and recognition of her own lamb is accompanied by increased activity within a subset of these cells in the mother's olfactory bulb. It is not known just how oxytocin might influence the electrical properties of the mitral cells or how this might produce the bond that forms between mother and offspring (DaCosta et al., 1996). Interestingly, a similar perceptual shift to a pheromonal cue may be at work in humans where it has been reported that one chemical, andosterone, is found attractive or repellent by women depending on their reproductive state.

Oxytocin plays another major role during reproduction, namely to trigger lactation in mammals. Here the causal chain of events between an organism's behavior on another's physiology is understood somewhat better. Oxytocin is released by magnocellular neurons in the hypothalamoneurohypophysial system (HNS). This system undergoes dramatic structural alterations in response to

gonadal steroids (reviewed in Hatton, 1995), including withdrawal of glia, synaptogenesis, and formation of dendrodendritic gap junctions. Significantly, all these changes occur during nursing of rat pups, and they reverse on weaning. The suckling of pups is a critical sensory input that initiates a neuroendocrine reflex arc. During suckling, short and intermittent high-frequency bursts of action potentials occur in oxytocinergic neurons in the mother's HNS. When these bursts become synchronized, a bolus of oxytocin is delivered to the mother's bloodstream where, on reaching the mammary glands, it promotes milk ejection.

Another dramatic plasticity produced by the suckling sensation occurs in the primary somatosensory cortex of the mother. Although there is no known link to hormonal circulation, the area devoted to the nursing mother's ventrum actually increases in representation by nearly twofold over that in nonlactating control and virgin animals. This cortical magnification is transient, reverting to its prior size after weaning (Xerri, Stern, and Merzenich, 1994). Thus, in both the triggering of a simple reflex arc as well as the more complex rewiring of regions of the cortex, the pups' behavior causes profound structural changes in the mother's brain.

Neuronal plasticity in real time

The aforementioned processes of parturition and lactation exemplify the complementary interaction between sensory stimuli, hormonal response, and behavior that unfold during development to ensure the survival of the newborn. Many examples of structural plasticity have been found beyond ontogeny, and our ability to recognize these events has benefited from their clear parallels with developmental processes. The mechanisms responsible for continued plasticity might be shared with normal development.

HORMONAL INFLUENCES ON SOCIAL DOMINANCE AND SEASONAL CHANGES It is not surprising that hormones, the key regulators of developmental plasticity, also are essential for many types of plasticity in real time. In these instances, the endocrine system, acting as an integrative force, serves to match an organism's internal state to its specific situation. The context for this action depends on its physical and social environment. Hormonal mechanisms allow adaptive responses to social factors in their physical context. The following examples are meant to illustrate how hormonal mechanisms allow adaptive responses to social factors, circumstances that require flexibility not achievable with fixed neural wiring.

In many social systems, it has been tempting to think that steroid molecules completely predestine the behav-

ioral role of the animal, particularly where social dominance is concerned. One popular notion is that higher levels of testosterone lead to dominance through increased aggressive behavior. It is not so simple. For example, in some systems, it is the social environment, composed of behavioral interactions between individuals, that provides the cues from which an individual recognizes its chance for elevated social status. Work by Cardwell and Liley (1991) in the stoplight parrotfish and our own teleost model system demonstrate that increased androgen levels actually follow, rather than precede, the assumption of dominance. These examples suggest that the fish's brain initially integrates sensory cues from its social interactions to delimit an endogenous social set point and this, in turn, instructs the control of hormones.

In some systems, increases in androgen both precede and follow social interactions. Work by Wingfield in Gambel's sparrows (reviewed in Wingfield et al., 1990) shows that the seasonal increase in day length stimulates testosterone production. Indeed, testis weight increases up to 600-fold, priming the animal for its upcoming reproductive tasks. However, later in the season, when testosterone has declined, contact with an unfamiliar, intruding male can immediately re-elevate those levels. That the hormone itself is not required for aggressive behavior has been demonstrated in castrated birds that also exhibit territorial behavior. Once again, it is clear that behavior, either of an individual or its conspecific, can initiate changes in the endocrine state.

Another example of plasticity is the seasonal change in the morphology of telencephalic nuclei that control song behavior, which has been reported for diverse species of songbirds. For all cases studied to date (cf. Brenowitz et al., 1998), testis size and circulating testosterone concentrations were greater in spring versus fall birds. The absolute volumes of three song nuclei in the brain (HVC, RA, and Area X), and their volumes relative to those of either the total telencephalon or three thalamic nonsong nuclei, typically are significantly greater in the spring than in the fall. Typically, song behavior also changes seasonally, and seasonal plasticity can be regarded as a common feature of the seasonally breeding songbirds studied.

SOCIAL ENVIRONMENT SHAPES NEURONAL STRUCTURE

*Natural behavior of *Haplochromis burtoni** To address the central question of how behavior influences the brain, our laboratory studies a cichlid fish, *Haplochromis burtoni* native to Lake Tanganyika in Africa. In their natural habitat, there are two kinds of males: those with

GnRH neuronal soma and gonad size

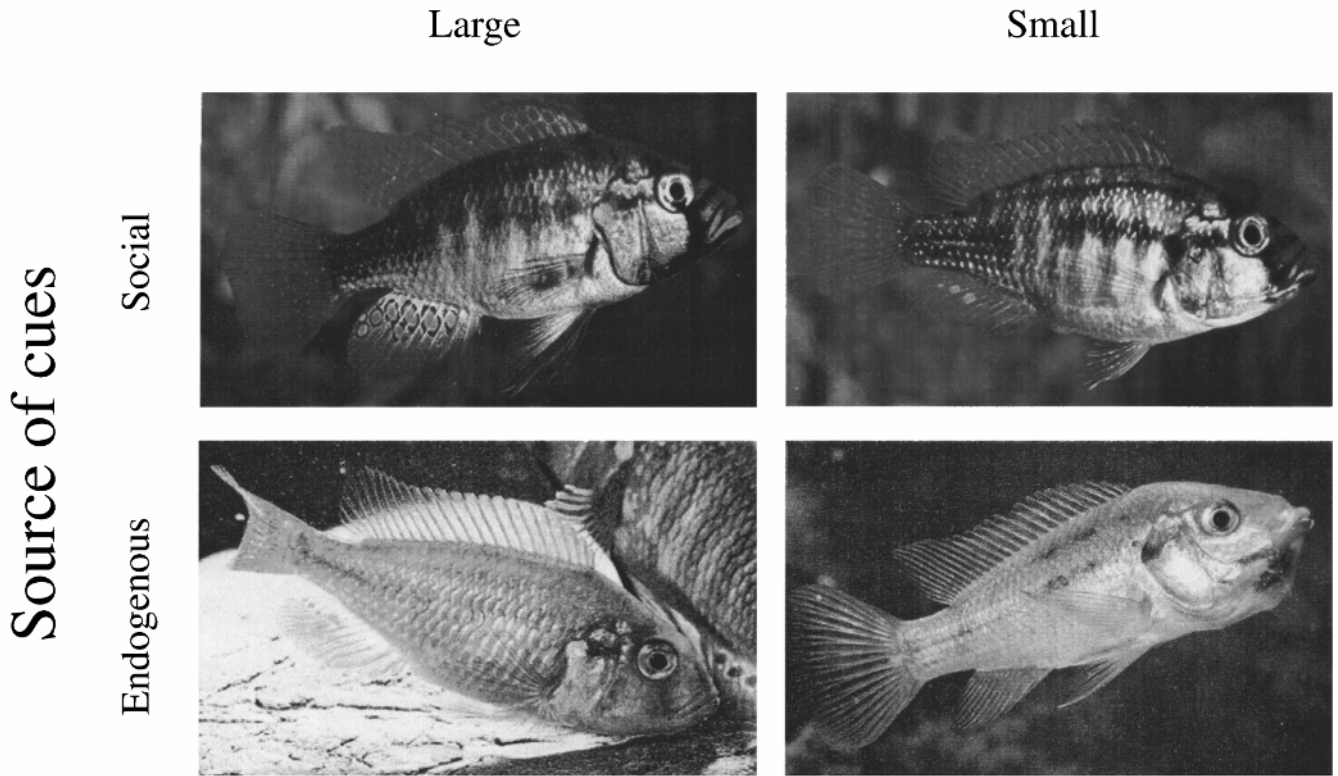

FIGURE 82.1 Social and reproductive states in *H. burtoni*. Male and female *H. burtoni* each are shown in two distinct reproductive states. Nonterritorial males and brooding females each possess small preoptic gonadotropin-releasing hormone (GnRH)-containing neurons. Territorial males and spawning females have larger GnRH neurons. GnRH neurons in females change size according to their reproductive cycle when

they shrink significantly in size during the 2-week period between spawning and brooding of fry. In contrast, neurons change size according to social signals in males. It takes more than 3 weeks for neurons to shrink in males undergoing a descent in social status but only 1 week to grow during social ascent.

territories and those without (Fernald and Hirata, 1977a, b). Territorial males, which make up only 10% of the males, are brightly colored, having a blue or yellow body color, dramatic black stripe through the eye, vertical black bars on the body, a black spot on the tip of the gill cover, and a large red patch just behind it. In contrast, nonterritorial males are cryptically colored, making them difficult to distinguish from the background and from females that are similarly camouflaged so that they appear nearly identical to females (figure 82.1). The animals live in a lek-like social system in which the brightly colored territorial males vigorously defend contiguous territories arrayed over a food supply (Fernald, 1977).

Social communication among these fish depends primarily on visual signals (Fernald, 1984). Territorial males are very active, performing at least 19 distinct behavioral acts during fast-paced social encounters (Fernald,

1977). They spend time digging a pit in the center of their territory, fighting with neighbors at their common territorial boundaries, chasing nonterritorial animals away, and soliciting and courting females. Solicitation and courtship behaviors are identified easily because the males display bright coloration patterns toward the courted female. Courtship includes “leading” the female toward the territory, and during “courting,” the male quivers his spread, brightly colored anal fin in front of the female. Females led into the territory feed by nipping at and sifting through the bottom cover.

Interestingly, nonterritorial males mimic this female behavior accurately enough so that the territorial males allow them to eat in the territory. Soon enough, the deception is discovered, and the female impersonator is chased off. If a genetic female responds to the entreaties of a male, he leads her into his pit and continues the elaborate courtship movements, swimming to the front

of the female and rapidly quivering his entire body with his anal fin spread in her view. As the pair disappears into the spawning pit out of direct view of the territory, other animals exploit this opportunity to feed energetically. The spawning male repeatedly interrupts his courtship behavior to chase intruders off his limited food supply. If physiologically ready and adequately stimulated, the female lays her eggs at the bottom of the pit, collecting them in her mouth almost immediately. After she lays several eggs, the male swims in front of her, again displaying the anal fins spots, his body quivering. The female then nips at the male's anal fin as though she mistakes his spots for uncollected ova. Thus, while attempting to "collect" the spots, the female ingests the milt ejected near them by the male and ensures fertilization. After several bouts of this alternating behavior, the female may go to the territory of another male to lay more eggs or depart from the territorial arena with the fertilized eggs to brood them (Fernald, 1984).

This brief description of the natural behavior of *H. burtoni* reveals the extensive role of visual signals in social interactions and how much the social scene governs the behavior of individual animals. Each behavioral act influences the next, both in the observed individual and in the animals involved in the interaction. During the behavior, a great deal of information is exchanged between individuals. What does the animal attend to and what are the consequences of that observation? Our studies have shown (Muske and Fernald, 1987) that the territorial males differ not only in their social displays, but also in the prominence of those signals to other viewers. Becoming and remaining socially dominant produces long-term physiological changes. Given the importance of the correct production and recognition of social signals, there must be mechanisms responsible for their development.

Developmental strategies in H. burtoni As young fish grow, social behavior of conspecifics regulates their growth (Fraley and Fernald, 1982). For the first 7 to 8 weeks of life, living in a group facilitates growth of males as compared with broodmates reared in total isolation. After this time, group-reared males that do not acquire and defend territories grow more slowly than those with territories do. Males that form territories develop their color patterns faster, weigh more, and have larger and more highly developed gonads than do animals reared under any other conditions. The growth of the animals under optimal conditions is dramatic and has resulted in novel developmental solutions over evolutionary time. This includes the addition of new cells to the lens and retina (Fernald and Wright, 1983; Fernald, 1993, 1989; Johns and Fernald, 1981). Such social control of maturation

and growth is widespread among animals and takes a variety of forms in different species. In *H. burtoni*, however, there are some unique effects of this social regulation of growth.

Males reared with adults show delayed maturation relative to those reared without adults, and moreover, these animals have smaller gonadotropin-releasing hormone (GnRH)-containing neurons in the preoptic area (POA) of the ventral hypothalamus (Davis and Fernald, 1990; figure 82.2). This finding suggests that the social control of maturation is reflected in changes in structures in the brain.

What are the salient sensory cues that a juvenile male fish perceives that influence its initial social state? In the laboratory, if juvenile males are reared alone, they develop into territorial males with all of the defining characteristics from large gonads to prominent lachrymal stripes. This shows that every male has the potential for social dominance, that this is the default developmental pathway, and that any genetic influence on dominance is negligible in comparison to social cues.

We have begun to dissect these social cues by sensory modality to determine the ones responsible for suppressing nonterritorial males and have discovered that, in addition to visual cues, tactile stimuli play a part (Davis and Fernald, unpublished observations, 1989). Thus, if a cohort of young fish is raised in the same aquarium as an older established community, the young males remain nonterritorial, as stated previously. If, however, the two groups are separated by a fine mesh net, one that allows visual and chemical contact and even permits threat displays across the barrier, they quickly learn that the would-be bullies on the other side of the tank are unable to chase and bite them. Freed from the threat of aggression by the big territorial males, the younger fish form their own communities where again, some 10% of the males escape maturational suppression and become territorial. In turn, these suppress the maturation of the remaining 90% of the males on their side of the net. Because both the older and younger communities have visual and chemical access to each other, these findings indicate that biting and nipping behaviors form some part of the suppressive signal imparted to nonterritorial fish.

Neuronal plasticity in adulthood In their natural environment, there are costs and benefits associated with territoriality. The benefits are that territorial males have a reliable food supply and through this, they are the only males that spawn. On the down side, the bright flashy colors and active behaviors of dominant males make them conspicuous to birds of prey. Predation of dominant males occurs at a significantly higher rate than does that of females and nonterritorial males (Fernald and

FIGURE 82.2 Comparison of the size of preoptic area GnRH-containing cells between dominant and nondominant males. Preoptic irGnRH cell soma sizes are compared between control (early maturing) males and experimental (maturation-suppressed) males, illustrating that in control animals, the cells are approximately 50% larger. Average soma diameters for the largest 30% of preoptic irGnRH cells for the six controls and

four experimental males are presented as a function of body weight. Bars indicate standard deviation. Testes weights are plotted on the same graph. The contrast in testes weights between the two groups is even more striking, with the low values for experimental males reflecting extreme hypogonadism. (Adapted from Davis and Fernald, 1990.)

Hirata, 1977b). When it occurs, the vacated territory is an open opportunity for a formerly suppressed nonterritorial male to make a dramatic switch in social state. Within seconds, the previously nonterritorial animal produces an eyebar and exhibits aggressive behavior. What endogenous changes accompany this outward transformation?

To understand the role of social status in determining reproductive state in older animals, adult males were changed from territorial (T) to nonterritorial (NT), or vice versa. To do this, T males were moved into communities with larger T males, as a result of which they became NT (T \rightarrow NT). Correspondingly, NT males were moved to new communities consisting of females and smaller males, which they could dominate, as a result of which they became T (NT \rightarrow T). In each case, the subjects remained in the altered social setting for 4 weeks, after which the size of GnRH-containing cells was measured (Francis, Soma, and Fernald, 1993).

Mean soma size of both the POA immunoreactive gonadotropin-releasing hormone (irGnRH)-containing

neurons (figure 82.3) and gonadosomatic index (GSI) (figure 82.4) were significantly larger in the control T males than in the control NT males. In another irGnRH cell group located in the terminal nerve in the telencephalon, there was no difference in mean soma sizes between T and NT males, indicating that the status-linked variation in soma size is not a general property of GnRH-containing neurons but instead is confined to the POA population.

In fish subjected to social transitions, experimentally induced T males (NT \rightarrow T) showed GnRH neuronal soma sizes and GSIs similar to control territorial males. This indicates that within 1 month, endogenous changes occur that equip the newly dominant male with the physiological capacity appropriate to his new social state. Conversely, in animals undergoing a downgrade in social status (T \rightarrow NT), GnRH neurons shrank to sizes that were insignificantly different from control nonterritorial males, and so did their gonads. Thus, social status determines both soma size of POA irGnRH neurons and GSI, and these effects are reversible. The relatively

FIGURE 82.3 Comparison of the size of preoptic area GnRH-containing cells between males following a transition between different social states. Three-dimensional plot of mean soma sizes of preoptic area (POA) irGnRH neurons, showing significant differences between T and T \rightarrow NT males and between NT \rightarrow T males. Percentage of individuals with mean soma size in

a given size bin are plotted for each treatment condition. There are no significant differences between T males and their experimental counterparts (NT \rightarrow T) or between NT males and their experimental counterparts (T \rightarrow NT). (Adapted from Francis, Soma, and Fernald, 1993.)

larger testes and irGnRH neurons characteristic of T males is a consequence of their social dominance, and when this dominance advantage is lost, both neurons and testes shrink.

Because the precipitating event in these studies was the experimentally manipulated change in social status, it is clear that in these teleosts, social state can initiate changes in endocrine state. However, such changes in social and endocrine systems interleave so fluently that they suggest a complex nexus of interactions rather than a linear chain of control. Thus, GnRH-containing neurons in the hypothalamus of adult territorial males both influence and are influenced by circulating gonadal hormones. We know this because castration of territorial males caused GnRH neurons to increase in size (Soma et al., 1996). This neuronal hypertrophy in castrated animals was prevented either by testosterone (T) or by 11-ketotestosterone (KT) treatment. Estradiol (E2) treatment did not reduce GnRH cell size in castrated animals. These results (figure 82.5) indicate that androgens reduce the size of GnRH cells through negative feedback. Because E2 had no effect, androgen influence on GnRH cell size appears to be independent of aromatization.

These data are consistent with the hypothesis that the set point for hypothalamic GnRH cell size is determined by social cues and that this set point is maintained by means of negative feedback by gonadal androgens. Territorial males have large GnRH-containing neurons *despite* high circulating androgens, not because of them (figure 82.6).

The aforementioned castration experiment was performed on territorial males. Enlarged GnRH neurons resulted, and although the mean soma sizes were even slightly bigger than those in control territorial males, their large size is in concert with the social dominance of the animal. To test whether GnRH neuronal cell size and social state can be dissociated, the castration experiment was replicated, this time using nonterritorial animals. After surgery to remove gonadal tissue, the fish were returned to the social settings from whence they came, ensuring that they remained nonterritorial. Behavioral observations confirmed that these animals indeed were submissive. Two weeks later, the fish were killed and the brains were examined for the sizes of the GnRH neurons in the POA. The number of animals that survived the surgical intervention followed by restoration to the community tank was small, and thus, the

FIGURE 82.4 Comparison of the gonad size between males after a transition between different social states. Three-dimensional representation of gonadosomatic index (GSI) data showing significant differences between T and T \rightarrow NT males and between NT and NT \rightarrow T males. Percentage of animals

results are preliminary. They suggest, however, that the GnRH neurons grew to be insignificantly different from those seen in territorial males (Yu and Fernald, unpublished observations, 1998). Thus, through experimental manipulation, it appears that GnRH neuronal soma size and social behavior can be uncoupled.

In *H. burtoni*, the regulation of growth and development may be adaptive in their habitat, where territorial space is limited. In the shore pools where these animals live, only a fraction of the males can breed at any time. As aforementioned, these breeding males appear to be particularly vulnerable to avian predators (Fernald and Hirata, 1977b), and hence territorial ownership may be relatively brief. Thus, there may be a selective advantage for males to have a retarded growth rate until they have an opportunity to become territorial, whereupon they grow rapidly.

Interestingly, after our original observation, we analyzed in more detail the rate at which social interactions influence the GnRH cell size. We recently have shown that the rate of cell size change is a function of the direction of the social transition (Nguyen et al., unpublished observations, 1996). Animals moving from nonterritorial to territorial status achieve the changes in GnRH-containing cell size (cf. figure 82.3) in just 7 days, whereas

within a given 0.2 magnitude range are plotted for each treatment condition. There are no significant differences between T males and their experimental counterparts (NT \rightarrow T) or between NT males and their experimental counterparts (T \rightarrow NT). (Adapted from Francis, Soma, and Fernald, 1993.)

those animals moving from territorial to nonterritorial may require 4 weeks until completion. This result is intuitively satisfying because there is such a distinct selective advantage to being a territorial male. Preliminary analysis of the behavior of animals that are moving in either direction is quite instructive. Many territorial males that have lost status continue to act territorial, even if only in concealed locations and at times when they are not being scrutinized by the new dominant male.

In sum, these data suggest that external social signals are transduced into at least two different pathways in *H. burtoni* males—one hormonal, determining the reproductive state of the animal, and the other behavioral. While in intact animals, the two pathways are correlated and the hormonal one serves to maintain the relevant physiology that goes along with social state, it is possible to dissociate the circuitry by experimental intervention, for example, castration of nonterritorial males. Further support that the two systems can be dissociated comes from work in *H. burtoni* females in which the social circuit appears to be muted or missing while the endocrine circuitry shows parallel plasticity to that seen in males.

In contrast to males, female *H. burtoni* do not appear to have differences in social status. They spend most of their time at the fringes of the dominant male's territory

FIGURE 82.5 Relationship of hormonal and social treatments as seen in GnRH-containing cell sizes. Soma area of POA ir-GnRH neurons plotted as a function of experimental treatment. Values shown are mean \pm SE. Castrated animals (Castrate, $n = 4$) had significantly larger mean soma areas than intact sham-operated controls (Sham, $n = 5$), and hormonal treatments in castrates had differential effects on POA irGnRH cell size. In castrates treated with testosterone (Castrate + T, $n = 4$) or 11-ketotestosterone (Castrate + KT, $n = 4$),

androgen replacement significantly reduced neuronal hypertrophy. In contrast, castrates treated with estradiol (Castrate + E2, $n = 4$) had significantly larger mean somas than the sham group. For each subject, approximately 100 POA irGnRH cells were measured (see Soma et al., 1996, for methods). Groups that are significantly different from the sham group are indicated with an asterisk (*). (Mann-Whitney U test, $p < .05$). (Adapted from Soma et al., 1996.)

FIGURE 82.6 Integration of social and hormonal cues in regulating GnRH-containing cell sizes. Proposed model of GnRH regulation in male *H. burtoni*. Neurons in the hypothalamic preoptic area integrate both social and hormonal signals to regulate GnRH release. In this model, the set point for the GnRH level is determined by social signals, and the maintenance of the GnRH level at this setpoint is achieved by negative feedback from gonadal androgens. (Adapted from Soma et al., 1996.)

where they school with nonterritorial males. As described previously, they move into territorial waters territories only to feed or spawn. This absence of social difference among females prompted the question: Are

GnRH neurons in female *H. burtoni* similarly plastic to males and, if so, what regulates changes in cell size? As aforementioned, a ripe female lays her eggs and then takes them into her mouth for fertilization and brooding. The brood is carried for approximately 2 weeks before being released. Changes in female appearance that accompany these reproductive states are due to physiological rather than social events. Thus, differences in body color, which in males reflects reproductive status, do not occur in females. Instead, a female that is ready to spawn has an enlarged abdomen, caused by the presence of ripe eggs. Later, after spawning, females with distinctively large mouth cavities filled with fry are not ready to spawn and avoid males.

Because females do not engage in the aggressive social interactions that drive male GnRH cell size, it is possible that they might not show the same plastic changes. GnRH cell size then would be sexually dimorphic, increasing in females simply as a function of development and becoming stable at maturity. This would contrast with the lifelong potential for plasticity seen in males.

Alternatively, because GnRH cell size in males is correlated with both social and reproductive status, cell size in females might fluctuate according to the female reproductive cycle.

To study possible changes in cell size in female *H. burtoni*, we analyzed cell size as a function of reproductive state in females (White and Fernald, 1993). Although there is some contribution of body size to the cell size changes, body size differences do not account for all the observed changes. Soma sizes in spawning females typically are twice as large as those in females carrying broods (figure 82.7), whereas postreproductive fish have the largest neuronal soma sizes. These changes occur within the 2 weeks it takes to brood a clutch, and the differences in GnRH neuronal soma size are comparable to those seen between dominant and subordinate males.

TRANSDUCTION OF SOCIAL SIGNALS INTO CELLULAR ACTION It seems clear that social encounters in particular social contexts have a profound effect on the behavior, reproductive potential, and brain structures in *H. burtoni*. How are these behavioral acts transduced into the proper cellular and molecular signals? For social behavior to have consequences in the brain and reproductive system requires an endogenous mediator that fluidly tracks social events and produces a signal, that, when integrated over time, sculpts changes in gene expression. Several lines of evidence suggest that the glucocorticoid stress hormone cortisol might serve this function. First, increased secretion of cortisol is a primary indicator of stress in teleost fish (reviewed in Wendelaar Bonga, Balm, and Lamers, 1995). Changing social settings can produce changes in cortisol levels in mammals (Alberts, Altmann, and Sapolsky, 1992; Gust et al., 1993; Johnson et al., 1996; Manogue, Candland, and Leshner, 1975; Sapolsky, 1986, 1993), birds (Schwabl et al., 1988), and fish (Pottinger, 1992, and reviewed in Billiard, Bry, and Gillet, 1981; Schreck, 1981). Stress suppresses the reproductive axis (reviewed for mammals, Rivier and Rivest, 1991; Sapolsky, 1993; for newts, Moore and Miller, 1984; for fish, Leitz, 1987; Pickering et al., 1987). Finally, stress steroids can alter gene expression by binding to intracellular glucocorticoid receptors, leading to dimerization, nuclear entry, and transcriptional activation or repression of genes bearing consensus elements in their upstream promoter regions (Meisfeld et al., 1986). To understand how social opportunity translates into physiological change in male *H. burtoni*, we manipulated the social setting and measured stress response with cortisol production and reproductive potential with the production of GnRH and gonad size (Fox et al., 1997). Our results show that cortisol levels depend on both individual dominance and reproductive status and social stability,

and that the reproductive opportunity of any individual hinges on temporal features of the social situation.

Support for the hypothesis that cortisol may be a key intermediate factor responsible for converting social interactions into a physiological change is that territorial males have low basal levels of cortisol whereas nonterritorial individuals have more varied and generally higher levels (Fox et al., 1997). Although dominant animals must continuously defend their territories through aggressive interactions with their territorial neighbors, it appears that the ritualized nature of these displays spares them from stress relative to their harassed and nonreproducing counterparts.

To understand the interaction of social behavior and reproductive physiology and brain structure, we compared animals in a variety of social settings over time (Fox et al., 1997). Our results show that in *H. burtoni*, stress depends not only on the social state of the individual, but also on the stability of the social community in which the animal lives. In addition, our data extend previous reports on the relationship between social and reproductive states in male *H. burtoni* into more complex social arenas because in all social settings, Ts had larger irGnRH-containing neurons and GSIs than NTs. Taken together, these results suggest that cortisol may serve as an endogenous signal relating the social environment to an animal's social status or internal reproductive state.

The distinct stress profiles of male fish in different social contexts indicate that cortisol levels responded to social dynamics. In all stable settings, Ts had lower serum cortisol than NTs (figure 82.8), but the emergence of this difference varied depending on the experimental group and the degree of social stability. Among social pairs, the cortisol difference was significant only during the second week of pairing among older fish, suggesting that stress levels decreased in Ts and increased in NTs as social relationships became established. This idea is borne out in community settings, where the development of social stability was explicitly examined. In high-density tanks, fish acclimated for 2 months before the start of the experiment. As a result, societies already were stable when initial observations were made, as seen in the high stability index (1.54; figure 82.8). In these tanks, Ts and NTs had significantly different levels of cortisol overall. In contrast, observations of the low-density tank began early enough to document the establishment of the social hierarchy. Switches in social state initially were frequent as males struggled for dominance. When emergent Ts succeeded in maintaining their territories over several weeks, the stability index increased from below 0.5 to 1.33, close to the stabilized, high-density tanks. At the same time, significant differences between T and NT cortisol levels became apparent. Thus,

FIGURE 82.7 Comparison of GnRH-containing neurons between spawning and brooding females. Photomicrograph showing irGnRH cells in a spawning (A) and a brooding (B) fish. Immunoreactive GnRH cells were labeled with a primary

antibody to GnRH and visualized via a 3,3'-diaminobenzidine reaction. Scale bars, 20 μm . (Adapted from White and Fernald, 1993).

early in the process of establishing a social hierarchy, both social relationships and rank-related stress levels stabilized.

In addition to corresponding to the social stability of a community, cortisol levels also reflected the social state of individual fish. This is highlighted in the 22 cases in which blood samples were taken before and after each spontaneous switch in social status (figure 82.9). In general, cortisol concentration is a noisy variable, varying widely *between* fish, so it is instructive to compare levels associated with the T and NT state in *the same* individual as it undergoes a social transition. In 18 of these cases, cortisol levels were lower within a male when he was T than when he was NT.

Because cortisol levels both track the dynamics of the overall social scene and correlate with individual social status, it is possible that integration of the cortisol signal could serve as an endogenous determinant of behavioral or reproductive state. If stress physiology predicts social status (Johnson et al., 1996), individuals with lowered cortisol responses should preferentially become dominant. Alternatively, if stress levels *result* from social status, once *any* individual becomes T, he may lead a less stressful life.

The size of GnRH-containing neurons in the POA of male *H. burtoni* also reflects social experience: Ts have significantly larger average neurons than NTs in each of the experimental set-ups tested (Fox et al., 1997). As with cortisol levels, the difference in GnRH neuronal magnitude appears to correspond both to individual social state and to overall social environment. Differences were

most extreme when animals were maintained in pairs, followed by fish kept in high-density tanks with stable social structure. Maintenance of fish in a low-density tank showed the smallest, although still significant, difference. Interestingly, soma sizes for both Ts and NTs in community tanks tended to be larger than in the social pairs, raising the possibility that GnRH production scales with social setting. Because cortisol and GnRH cell size each reflect individual and overall social states, it is tempting to speculate that integration of the cortisol signal could lead to changes in GnRH neuronal size. In the hypothalamus, cortisol might produce effects on GnRH neurons directly (Ahima and Harlan, 1992; Chandran et al., 1994); alternatively, the hypothalamic stress factor corticotropin-releasing hormone could influence GnRH cell size (MacLusky, Naftolin, Leranthe, 1988; Rivier and Vale, 1984). It should be noted that in birds (Hahn et al., 1995) and reptiles (Denardo and Licht, 1993), it has been proposed that glucocorticosteroids can influence reproductive behavior without inhibiting reproductive hormones. In *H. burtoni*, however, the soma size and behavior are both different between Ts and NTs, which is not consistent with independent action of cortisol directly on behavior.

Future studies using implants either to block or augment cortisol levels should resolve whether and how cortisol might play a role in relating behavioral change to brain change. Further, examining cortisol levels in females who exhibit reproductively regulated cyclical changes in GnRH neuronal soma size but do not exhibit

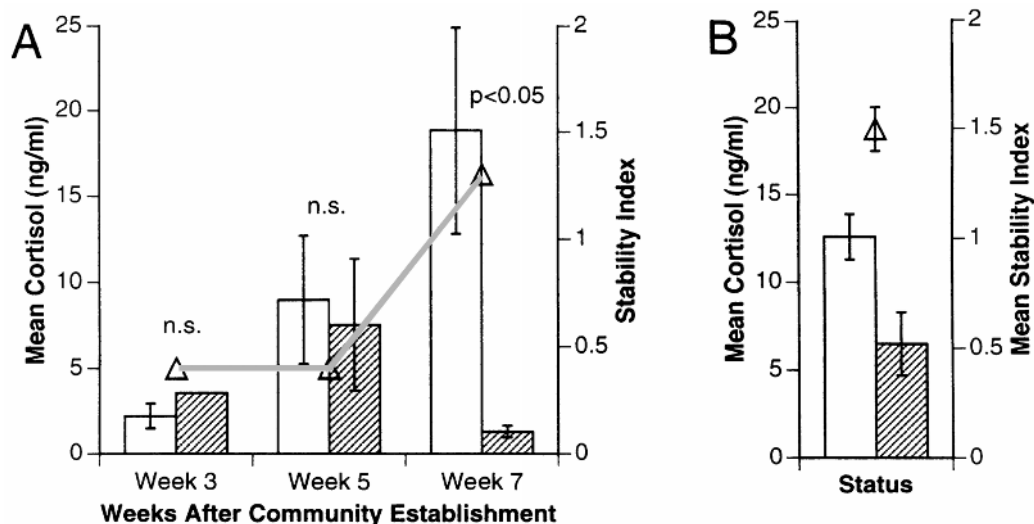

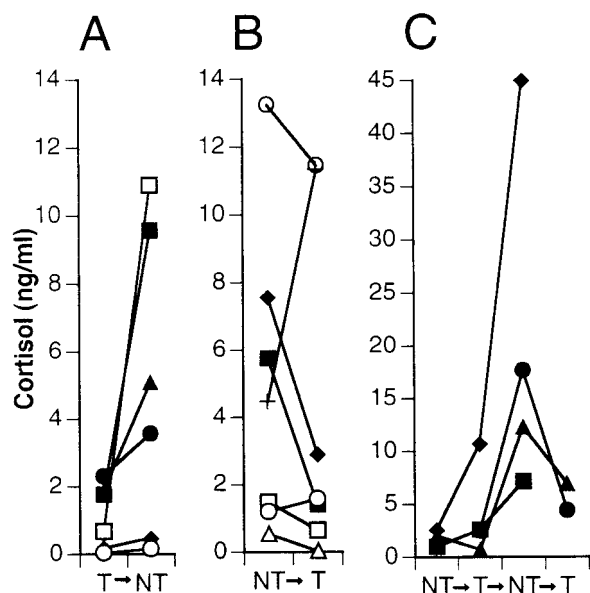

FIGURE 82.8 Stress levels in animals under different social conditions. Cortisol levels of NTs (open bars) and Ts (hatched bars) shown for (A) low-density communities and (B) high-density communities (averaged). In both cases, the stability index (see Materials and Methods) is superimposed on cortisol level

data. In the low-density setting, differences in cortisol levels are plotted over the course of 7 weeks. High-density communities had been established for 2 months prior to blood sampling and are fully stabilized. (Redrawn from Fox et al., 1997.)

Switches in Status

FIGURE 82.9 Cortisol levels in individual fish that switched social status. (A) Single switches from T to NT. (B) Single switches from NT to T and (C) multiple switches (note different ordinate scale in [C]). Fish had significantly higher cortisol levels as NT than as T ($p < .05$, Wilcoxon signed rank, using last switch if multiple switches per fish). (Redrawn from Fox et al., 1997)

differences in social rank (White and Fernald, 1993) also could distinguish effects restricted to reproductive, rather than social, states.

MOLECULAR CONSEQUENCES OF SOCIAL CHANGE

One necessary outcome of changes in social status is the regulation of GnRH gene expression. To test the hypothesis that social interactions ultimately regulate reproductive capacity through control of GnRH gene expression requires that social manipulations be combined with molecular measurements. We previously have shown that this fish has three distinct cDNAs that code for GnRH forms, each localized to a separate neuronal population (White et al., 1994, 1995). One of these three genes is expressed in the hypothalamic neurons that change size (GnRH-I), a second in the midbrain (GnRH-II), and a third in the forebrain (GnRH-III). Of these, only the function of GnRH-I, namely controlling reproduction, is known. With these genetic probes, we combined behavioral manipulations with measurement of gene expression to discover whether animals forced to change fate responded with changes in gene expression. In “undisturbed” colonies, T males have higher levels of GnRH-I mRNA than do NT males (White and Fernald, unpublished). Using a paradigm termed “certain fate,” we examined the time course of any changes

FIGURE 82.10 Levels of GnRH gene expression in males after experimentally induced switches in social state. The mean values of mRNA levels for GnRH-I for males switched from NT to T status. At both 3 and 7 days after switching, NT to T males have higher preoptic GnRH mRNA levels than their control NT counterparts.

in gene expression accompanying social change by switching the social states of males and then measuring changes in gene expression in individual animals using RNase protection assays. Seven days after being moved into a social setting, animals that went from NT to T had elevated levels of GnRH-I mRNA relative to their NT controls ($p < 0.002$, Mann-Whitney U test, one-tailed; figure 82.10). In contrast, there was no significant difference in expression levels of the other two GnRH forms (White and Fernald, unpublished). These preliminary data show that changing social status causes a change in gene expression that can be measured in individuals. This suggests that we may contemplate connecting behavior to molecular biology in a meaningful way.

This model system has revealed how changes in social state translate into changes at the cellular and molecular levels. However, we still do not know how many signals link the animal's perception of its social status to specific behavioral and endocrine changes.

Neuronal plasticity in the service of behavior

Understanding how behavior influences the brain requires analysis at three important time scales: evolutionary time, developmental time, and real time. The adaptive function of particular behavioral acts shaped over evolutionary and developmental time can suggest where to look for neuronal plasticity in real time, especially in brain regions controlling essential acts such as reproduction. We can expect social specializations in brains of all kinds of organisms. There are likely parts of all vertebrate brains that process social information so that unraveling the pathways that lead from social exchange to structural change within the brain should continue to

yield surprising insights about how the environment sculpts behavioral, cellular, and, ultimately, molecular changes in the nervous system.

What Sex Differences in Spatial Ability Tell Us about the Evolution of Cognition

DAVID F. SHERRY

ABSTRACT Human cognition is a collection of adaptations shaped by the selective pressures to which we have been exposed during our evolutionary history. Identifying these selective pressures, however, and determining the selective advantages conferred by the properties of human cognition is not easy. Sex differences in human spatial ability provide an opportunity to test evolutionary hypotheses about the evolution of human cognition. Men tend to perform better than women do on some tests of spatial ability, and sex differences in spatial ability occur in a variety of nonhuman animals. Males tend to perform better than females on tests of spatial ability in species of mammals in which males possess larger home ranges than females during the breeding season. These sex differences in spatial behavior and cognition are accompanied by a sex difference, in favor of males, in the relative size of the hippocampus. In species in which females are more active in spatial search than males, females possess a larger hippocampus than males. These results suggest that spatial ability and relative size of the hippocampus are evolutionary adaptations associated with spatial behavior and orientation. Findings with animals raise the question of whether sex differences in humans also may be adaptations to sex differences in spatial behavior. Men have larger home ranges than women do, and spatial ability in humans is sensitive to the effects of both testosterone and estrogen. These results suggest that sex differences in human spatial ability are the product of both natural selection and sexual selection and provide some insight into the evolutionary pressures that influenced the evolution of human cognition.

Sex differences in human reproductive behavior and physiology are not particularly controversial. Their existence, at any rate, is not a matter of dispute. Sex differences in cognition are a different matter and are debated hotly (Caplan, MacPherson, and Tobin, 1985). In the area of spatial ability, however, the existence of a consistent sex difference in performance is well established (Voyer, Voyer, and Bryden, 1995). On some tests of spatial ability, such as the Vandenberg version of the Shepard-Metzler Mental Rotations Test (Vandenberg, 1971), the mean performance of men can be as much as one standard deviation greater than the mean performance of women.

Alleged sex differences in human behavior and cognition sometimes are solely in the eye of the beholder and reflect nothing more than societal expectations and biases. Sex differences with a firm empirical foundation, in contrast, invite a search for their origin. In this chapter, I introduce evolutionary arguments that sex differences in human spatial ability, like sex differences in spatial ability in other animals, are a consequence of evolved differences in the reproductive roles of the two sexes. Sex differences in spatial ability are one among many legacies of our evolutionary origin and can help us understand why our cognitive apparatus takes the form it does. Human cognition in all its complexity is an adaptation, or more accurately, a host of adaptations, shaped by natural selection to deal with specific problems in our environment of evolutionary adaptedness ([EEA]; Tooby and De Vore, 1987). Sex differences may be a window through which we can glimpse our long-vanished EEA. Sex differences in human spatial ability are consistent with some, but not all, conjectures about human origins and may in this way provide insights about the evolution of human cognition.

The chapter begins with a discussion of spatial orientation in animals that illustrates the relation between reproductive behavior, home range, and spatial ability. This example, taken from the work of Gaulin and colleagues on *Microtus* voles, also introduces the topic of sexual selection and sexual selection for spatial abilities. In some voles, as in humans, males perform better than females on laboratory tests of spatial ability. A correlated sex difference is found in voles in the size of the hippocampus, a structure involved in a variety of cognitive functions, including spatial orientation. Superior performance by males on spatial tests is by no means universal, however, as shown by the second example. In brood parasitic cowbirds, females search for host nests and experience greater demands on spatial ability than males. The consequences of this sex difference in behavior are reflected in a sex difference in the size of the hippocampus that is the reverse of that found in voles: Female cowbirds have a larger hippocampus than males. In the final part of the chapter, I return to human

sex differences, present the evolutionary hypotheses that have been proposed for their origin, and describe how recent research on hormonal influences on human spatial abilities can be used to test these hypotheses.

Mating system, spatial ability, and the hippocampus

HOME RANGE SIZE AND SPATIAL ABILITY IN VOLES
Most voles in the genus *Microtus* are polygynous. The meadow vole (*M. pennsylvanicus*) is typical. During the breeding season, males expand their home ranges to encompass the home ranges of a number of females. Males compete with each other for mating opportunities by ranging widely and thereby encountering greater numbers of females. Female meadow voles gain no reproductive advantage by increasing the number of their mates—additional matings do not produce additional offspring—and their home ranges are considerably smaller than those of breeding males, approximately 200 m² compared with male home ranges of 600 m² or more (Gaulin and FitzGerald, 1986). Outside the breeding season, male meadow vole home ranges are the same size as those of females.

A few species of *Microtus* voles, however, like the pine vole (*M. pinetorum*) and the prairie vole (*M. ochrogaster*), are monogamous. Male and female pine vole home ranges are the same size, approximately 40 m², and mated pairs remain together on a territory they share with juveniles and subadults (FitzGerald and Madison, 1983). Male and female prairie vole home ranges are likewise the same size, approximately 200 m², and are shared by a male and female, both of whom provide parental care and exclude other adult prairie voles from the territory (Gaulin and FitzGerald, 1989). In a monogamous mating system, males gain no reproductive advantage from having a larger home range than females. Females that they encounter likely are mated already, and male reproductive success in a monogamous mating system is influenced more by the quality of parental care provided to the young than by the number of mating opportunities.

These differences in breeding system led Steven Gaulin and his colleagues to make a number of predictions about the evolution of spatial ability in voles; voles were selected as study organisms because evolutionary thinking indicated that they might be a particularly informative group of animals to examine. It may be that sex differences in spatial ability are an intrinsic part of male and female development, a consequence of how male and female brains develop. Alternatively, and this was Gaulin's line of reasoning, sex differences in spatial ability might occur only when there is selection for spatial ability that is specific to one sex only. Only under

these conditions would superior spatial ability in one sex be expected. In the absence of sex-specific selection, there should be no sex difference in spatial ability. Thus, the predictions were that male meadow voles should have better spatial ability than females because of selection to navigate successfully their large home ranges, whereas in the monogamous species there should be no sex difference in spatial ability.

A series of studies showed that male meadow voles perform better than females on a variety of laboratory maze tasks, although there is no sex difference in maze performance in either pine voles or prairie voles (Gaulin and FitzGerald, 1986; Gaulin and FitzGerald, 1989; Gaulin, FitzGerald, and Wartell, 1990). Superior spatial performance by males is a typical mammalian pattern. What is particularly striking is that in a monogamous breeding system, in which there is no selection for greater home range size in males, there is no difference in spatial ability. Sex-specific selection for range size in the polygynous breeding system of meadow voles is likely to be the origin of the sex difference in spatial ability observed in this species. Further experiments have shown that sex and species differences in the level of activity in the mazes cannot account for the occurrence of a sex difference in the polygynous species and its absence in the monogamous species (Gaulin, FitzGerald, and Wartell, 1990). Experiments also showed that vastly different amounts of spatial experience in laboratory-reared and wild caught prairie voles did not affect their maze performance (Gaulin and Wartell, 1990). The performance of males and females (which does not differ in this monogamous species) was not affected by experience with different-sized home ranges.

The difference in spatial ability between male and female meadow voles has evolved by sexual selection. Sexual selection, according to Darwin, accounts for the evolution of traits that contribute little to survival or longevity but instead provide an advantage solely in competition for mates. Sexual selection can be of two forms—traits that provide an advantage in contests with members of the same sex for access to mates and traits that increase reproductive success because individuals with the trait are preferred as mates by members of the opposite sex. The antlers of deer may have evolved because they provide males with an advantage in direct competition with other males, a process called intrasexual selection. The elaborate displays of birds of paradise may have evolved because males performing these displays are preferred as mates by females, a process called intersexual or epigamic selection (Andersson, 1994). The spatial abilities of male meadow voles thus are likely to have evolved under the influence of intrasexual selection because males compete for mates in the polygynous

meadow vole breeding system by traversing large home ranges in search of females.

Darwin proposed that if a trait had evolved by sexual selection, it would be expected to have some further properties. It obviously should develop to a greater degree in one sex than the other, it might be expected to appear at sexual maturity *not* before, its occurrence may be restricted to the breeding season, and it should be displayed to rivals or mates. These properties do not apply to all sexually selected traits. Sexually selected dimorphism in body size, for example, does not disappear outside the breeding season. The last property, concerning display, does not apply particularly well to male meadow voles' territories because the competition that male meadow voles engage in by having large home ranges is somewhat indirect. Indeed, competing males may never encounter each other. The first three properties expected under sexual selection, however, have been examined in some detail in voles. Territory size and spatial ability, as we have seen, are greater in male meadow voles than in females. Nonreproductive male meadow voles, as determined by examination of the testes, and males observed outside the breeding season, have territories approximately the same size as those of females (Gaulin and FitzGerald, 1988; Gaulin and FitzGerald, 1989).

In another polygynous breeding rodent, the deer mouse (*Peromyscus maniculatus*), males also have larger home ranges than females during the breeding season. Males in breeding condition acquire the Morris water maze task more quickly than females do, although outside the breeding season the sexes do not differ in their performance on the water maze (Galea et al., 1994; Galea, Kavaliers, and Ossenkopp, 1996). Galea and colleagues found, however, that the sex difference during breeding is due only in part to an improvement in male performance; part of the effect is due to a decline in performance by breeding females. The latter outcome is not predicted by sexual selection for spatial ability in males, although as we shall see later, it resembles one of the most interesting results in recent research on sex differences in human spatial ability.

SEX DIFFERENCES IN THE HIPPOCAMPUS Male meadow voles not only have larger home ranges and better spatial ability than females, they also have a different brain. In particular, they have a larger hippocampus than females, a sex difference that does not occur in the monogamous pine vole (Jacobs et al., 1990). This sex difference in hippocampal size, which is greater than expected on the basis of sex differences in brain size and body size, suggests that sexual selection on males in the polygynous meadow vole breeding system has had a se-

ries of propagating effects. Selection for increased home range size in males, spatial ability adequate to navigate this home range, and a hippocampus modified to cope with the navigational problems of a larger home range has produced a suite of interacting behavioral, cognitive, and neural traits. Merriam's and bannertail kangaroo rats (*Dipodomys merriami* and *D. spectabilis*) also breed polygynously and exhibit a sex difference in home range size, the home ranges of males being larger than those of females. As with meadow voles, males have a larger hippocampus than females in both species of kangaroo rat (Jacobs and Spencer, 1994). Male mongolian gerbils (*Meriones unguiculatus*) have a larger home range than females in the wild (Ågren, Zhou, and Zhong, 1989) and a larger hippocampus (Sherry, Galef, and Clark, 1996).

Brood parasitism and the hippocampus of cowbirds

The female brown-headed cowbird (*Molothrus ater*) is a very drab-looking bird, even by blackbird standards: grey-brown above with a hint of streaking on the breast and a throat slightly paler than the rest. The eponymous male is a striking iridescent black with a chocolate-brown head. The common names of birds typically show such male sex bias. But the brain and behavior of cowbirds exhibit a sex difference that not only runs counter to appearances, but also illustrates a general point about sex differences in spatial cognition.

Brown-headed cowbirds are brood parasites. Females lay approximately 40 eggs a year in the nests of other species (Scott and Ankney, 1980; Scott and Ankney, 1983) that then are hatched and raised by the host, usually at a cost to the host in the number of its own young that it can rear. Brown-headed cowbirds exploit more than 200 host species, capitalizing on the failure of the adoptive parents to discriminate a cowbird egg or nestling from their own. Female cowbirds search for potential host nests unassisted by males. Females have been observed sitting silently in the forest canopy watching nest building by potential hosts, walking on the forest floor scanning the canopy, and flying noisily into understorey shrubs, presumably to flush incubating birds from their nests (Norman and Robertson, 1975). Synchronizing laying with the stage of progress of the host nest is important for cowbirds. Placing an egg in a nest under construction can cause the host to simply cover it over with nest material, or desert the semicompleted nest and start another. Laying too late in the host's nesting cycle can result in the cowbird egg being abandoned when the host's young hatch and fledge. Female cowbirds evidently prefer a nest containing at least one but not more than two host eggs (King, 1979), although they are prolific layers and often place eggs in less than ideal sites.

Females lay at or before dawn, then spend the rest of the morning searching for host nests before leaving the forest and edge habitats, where most host nests are found, to feed with males in grain fields and livestock yards often far from areas with potential host nests. Females probably travel at dawn to a nest or nests that they have located on a previous day and lay an egg quickly during the incubating parent's absence. There is little time in the early light of day to search for a suitable host nest, and females likely lay in nests that they have located previously.

All this leads to the conclusion that female cowbirds probably remember for at least 1 day, and possibly many days, the spatial locations of some number of suitable host nests. Males do not participate in the search for host nests, but instead follow females in their daily routine. We hypothesized that natural selection for the ability to locate and remember the locations of potential host nests may have affected spatial ability and the brain of female cowbirds in a way that has not occurred in males (Sherry et al., 1993). Specifically, we proposed that the hippocampus of female cowbirds would be larger than that of males, after allowing for any sex difference in overall brain or body size.

To determine whether any sex difference in hippocampal size that might be found in cowbirds is related to search for host nests by females requires some further information. Perhaps the hippocampus is larger in females in all blackbirds, or in all birds for that matter. As with the effects of breeding system on spatial ability in voles, the appropriate way to answer this question is comparatively. We compared the hippocampi of males and females in two species of blackbirds that are not brood parasites, red-winged blackbirds (*Agelaius phoeniceus*) and common grackles (*Quiscalus quiscula*). Red-winged blackbirds, grackles, and cowbirds are all members of the same tribe, Agelaiini, within the same blackbird subfamily, the Icterinae. The logic of this comparative analysis is that with a shared phylogenetic history, differences between species can be attributed more readily to current ecological or behavioral differences between the species, in this case brood parasitism (Harvey and Krebs, 1990).

The results showed that the hippocampus of female brown-headed cowbirds was, in fact, significantly larger than that of males and that this difference was greater than could be attributed to sex differences in brain size or body size. Neither red-winged blackbirds nor common grackles showed any indication of a sex difference in hippocampal size (Sherry et al., 1993).

What is striking about this result is that the direction of the sex difference runs counter to all previously reported sex differences in hippocampal size. In meadow

voles, deer mice, kangaroo rats, gerbils, and other mammals the sex differences that occur in hippocampal size favor males. As we saw earlier, this sex difference probably is a consequence of selection on males for large home ranges and matching spatial ability. The occurrence of greater hippocampal size in female cowbirds shows that it is not sex per se that determines hippocampal size, but an evolutionary history of differential use of space by the two sexes. When females are the sex with greater demands on spatial ability, as in cowbirds, they are the sex found with a relatively larger hippocampus.

Altogether, six species of cowbird are found in the New World. The shiny cowbird (*Molothrus bonariensis*) is a generalist parasite, like the brown-headed cowbird. Shiny cowbirds parasitize more than 150 different species of host, and females search for potential host nests without male assistance (Mason, 1987). The screaming cowbird (*M. rufoaxillaris*), in contrast, is a specialist. It parasitizes only one species, and this species is itself a cowbird, the bay-winged cowbird (*M. badius*). Male and female screaming cowbirds search together for bay-winged cowbird nests (Mason, 1987), and this cooperative search behavior, in contrast to search by females only in brown-headed and shiny cowbirds, reasonably might be expected to eliminate any sex difference in the hippocampus due to sex-specific spatial behavior. Bay-winged cowbirds, the sole host of screaming cowbirds, are not nest parasites but incubate their own eggs and raise their own young (Fraga, 1991). Bay-winged cowbirds nest colonially, however, and sometimes usurp the nests of other colony members. Two remaining species, the bronzed cowbird (*M. aeneus*) and the giant cowbird (*Scaphidura oryzivora*) parasitize intermediate numbers of hosts, approximately 40 to 50, but they play no further part in this story.

Shiny, screaming, and bay-winged cowbirds are all found in Argentina and were collected in the field during the breeding season by Rebores and colleagues (1996). They determined the size of the hippocampus in males and females of all three species and found that, overall, the hippocampus was larger relative to the size of the forebrain in the two brood parasites than in the nonparasitic bay-winged cowbird. As predicted, females had a larger hippocampus than males only in the shiny cowbird, the generalist parasite in which females search alone for host nests. No sex difference in relative hippocampal size occurred in screaming cowbirds, the specialist brood parasite in which both sexes search for host nests, or in the nonparasitic bay-winged cowbird. Similarly, in other passerine birds in which there are no ecological or evolutionary reasons to expect a sex difference in spatial behavior, like the black-capped chickadee

THE TYPICAL SEX DIFFERENCE ON THE MENTAL ROTATION TEST

FIGURE 83.1 The sex difference in human spatial ability can be large on some tests, even compared with morphological sex differences such as height. Performance of adult men and women on the Vandenberg version of the Shepard-Metzler mental rotation test is shown for two representative studies (left). The mean score for women ($N = 672$) was 65% of that for men ($N = 359$) in the study by Sanders and associates (1982).

(*Parus atricapillus*), no sex difference occurs in the size of the hippocampus (Petersen and Sherry, 1996).

Sex differences in human spatial ability

In humans, men and boys generally perform better on standardized tests of spatial ability than women and girls do. Although there is debate about the origin and correct interpretation of this difference, a meta-analysis by Voyer and associates (1995) shows that it is reported consistently in experimental work. Males typically perform better than females on tests such as the Shepard-Metzler task, which requires subjects to view a drawing of a three-dimensional object and then indicate in multiple-choice fashion which of several drawings portray possible rotations of the original object. Sex differences on tasks such as this are reliable and have remarkably large effect sizes (figure 83.1).

It probably is no coincidence that men and boys have greater home ranges than women and girls do (Gaulin and Hoffman, 1987). Fossil evidence of the modification of human limb bones by the loads due to locomotion and similar modification in the bones of contemporary humans, indicate greater ranges in males than in females from the middle Paleolithic to the present (Ruff, 1987).

THE SEX DIFFERENCE IN HEIGHT OF ADULT MEN AND WOMEN

The mean score for women ($N = 19$) was 75% of that for men ($N = 19$) in the study by Moffat and Hampson (1996). The mean height (right) of women is 93% that of men (Tanner, 1990). Error bars equal 1 standard error of the mean and are too small to appear in the height data. (Reprinted from Sherry and Hampson, 1997.)

In both contemporary urban societies and in developing countries, men have larger home ranges than women (Munroe and Munroe, 1971; Dab and Robert, 1997).

The relations among performance on standardized tests of spatial ability, range size, and navigation in humans is not entirely clear. Males could show better performance on standardized tasks because they have larger ranges and more real-world spatial experience, or males could have larger ranges and more spatial experience because they are better at the kind of problems measured in standard tests. It also should be emphasized that paper-and-pencil tests of spatial ability are not necessarily measures of the capacity for real-world orientation and navigation. They may measure spatial abilities that are quite independent of the cognitive capacities required for orientation and navigation within a home range. The picture is not entirely discouraging, however. Performance on standardized mental rotation tasks is correlated with performance on slightly more realistic navigation problems, such as navigation through a virtual environment presented on a computer screen (Moffat, Hampson, and Hatzpantelis, 1998), and range size is correlated, at least in males, with performance on standardized tests (Dab and Robert, 1997). Nevertheless, further research on the relation between paper-and-pencil

tests of spatial ability and navigation and orientation by humans clearly is required.

With these provisos in mind, it nonetheless is notable that observations on sex differences in spatial ability and home range size in polygynous mammals raise the possibility that there may be an evolutionary explanation for sex differences in human spatial ability. It is possible that in the environment of evolutionary adaptedness, human males and females were exposed with some consistency to differential selection for spatial ability and that one effect of such selection is a sex difference among contemporary humans in performance on spatial tasks in the laboratory. Elizabeth Hampson and I recently assembled seven evolutionary hypotheses that have been advanced to account for sex differences in human spatial abilities (Sherry and Hampson, 1997). Three of these hypotheses propose that the sex difference is a consequence of sexual selection for increased range size in males. Two propose that the sex difference is the outcome of a division of labor between the sexes in foraging. Two further hypotheses propose that life history differences between the sexes, specifically dispersal and reproductive roles, have selected for a sex difference in spatial ability.

SEXUAL SELECTION Gaulin has extended ideas derived from work on rodent breeding systems to humans by noting that humans are polygynous to some degree, that increased mating opportunities may be available to human males by increasing their range size, and that males do indeed have larger home ranges than females (Gaulin, 1992). Competition among males for mates thus may have resulted in sexual selection for spatial ability in human males, an effect that has not occurred in human females. Females, unlike males, do not obtain an increase in the number of their offspring from an increase in the number of mates and so are less exposed to the effects of intrasexual competition for mates.

Another sexual selection hypothesis suggests that human males benefited evolutionarily from increased range size, but in this case, the function of increased range size was to attack other groups to decrease local competition for resources or to obtain mates (Alexander, 1979). Thus male warfare also might impose selection restricted to males on spatial ability and cognition.

Finally, epigamic sexual selection, based on female choice for mates, may have selected for male spatial ability. The anthropologist Kirsten Hawkes has made the interesting observation that in some societies, the benefit of male hunting success is not provision of meat to the hunter and his immediate family but instead an increase in status for the hunter, obtained by distributing

meat to other members of the group (Hawkes, 1990; Hawkes, 1991). The nutritional benefits to the hunter and his family may be insignificant. What is significant is that successful male hunters enjoy high status and are sought after as mates. In this scenario, sexual selection acts through female choice. Hunting, with its associated ranging ability and spatial skills, becomes a sexually selected display, more akin to the display of male birds of paradise than to the competitive ranging behavior of male meadow voles.

FORAGING A division of labor between the sexes in foraging occurs in hunter-gather societies: males usually, but not always, range more widely to capture game whereas females search for nonmobile foods. Superior male spatial ability in this hypothesis is attributed to sex-specific selection on males for long-range navigation and possibly throwing skills (Lovejoy, 1981; Jardine and Martin, 1983).

An interesting variation on the foraging hypothesis proposes that females should show superiority on spatial tasks that correspond more closely to foraging tasks performed by females than do the usual tests of spatial ability (Silverman and Eals, 1992; Eals and Silverman, 1994). Silverman and colleagues have shown that women perform better than men on tests that require remembering the location of objects in a spatial array and detecting when the location of these objects has been changed. Tasks of this kind have not been widely used to examine sex differences in spatial ability but clearly suggest that spatial ability and sex differences in spatial ability may not be all of a kind.

LIFE HISTORY Dispersal from the place of birth to the eventual site of adult residence is sex biased in many birds and mammals (Greenwood, 1980). In mating systems in which defense of a resource, such as a territory, is essential for mating, females tend to disperse during the late juvenile or early adult period whereas males remain in the natal area. In mating systems that depend on the physical defence of mates rather than resources, males tend to disperse and females remain in the natal area. It thus has been suggested that sex-biased dispersal, and the demands it makes on orientation, may be responsible for sex differences in spatial ability. This hypothesis is difficult to sustain for humans because although it clearly supposes selection for superior spatial ability in the sex that disperses, in humans it is females that disperse farther than males between birth and adult mating and child-rearing (Koenig, 1989; Clarke and Low, 1992). This effect can be observed in a variety of cultures and is apparent even in contemporary North America. It is also probably an oversimplification to

suppose that animal dispersal, in which late juvenile and early adult animals leave the natal area in search of suitable habitat elsewhere, is an appropriate model for human dispersal. In humans, dispersal by females is likely to always have occurred along established routes of contact between groups, probably under the control of male kin, and not by a process of cross-country orienteering.

Pregnancy, lactation, and parental care are life history traits that differ between the sexes in humans and may have had important effects on human spatial ability. Under this hypothesis, a large home range was selected against in women because a large home range and a high degree of mobility may impose energetic costs that reduce fertility, interfere with cyclicity, and compromise pregnancy and parental care (Sherry and Hampson, 1997). A reduction in mobility at critical times during the reproductive life of women might provide benefits in terms of reduced risk of predation, accident, encounter with males of other groups, and other possible hazards. This hypothesis thus supposes that spatial ability is not so much enhanced in males as reduced in females because of the sex-specific advantage to females of reduced range size.

TESTING THE HYPOTHESES Although the evolutionary origins of sex-specific human spatial abilities are remote and seemingly inaccessible, recent research on development and hormonal influences on human spatial abilities provide data that can be used to test some of these ideas about the evolutionary origin of sex differences in human spatial ability.

As mentioned earlier, Darwin believed that traits that have evolved by sexual selection should tend to appear at sexual maturity, not before. Therefore, the sexual selection hypotheses all predict that the advantage in male spatial ability should emerge at sexual maturity and perhaps exhibit some effect of testosterone in males.

In their meta-analysis, Voyer and associates (1995) grouped subjects by age in three categories: under 13 years of age, 13 to 18 years, and older than 18 years of age. For mental rotation tasks, the sex difference is significant in all three age groups, but the effect size increases with age. For tests of spatial perception, the effect size also increases across the three groups. The sex difference is significant at 13 to 18 years, and older than 18 years, but not under 13 years. For spatial visualization, the effect size likewise increases across age groups, but the sex difference is only significant for the older than 18 years group. There thus appears to be some indication that the sexes diverge in spatial ability around the age of puberty, as predicted by the sexual selection hypotheses, although the data do not permit a positive identification of its onset with the timing of puberty in

males. If anything, the age of onset is early, rather than late, adolescence may correspond more closely to puberty in girls than in boys.

Hormonal data show that testosterone can have an enhancing effect on human spatial ability. Some of these androgenic effects are revealed by the effects on spatial ability in girls of high androgen levels experienced in utero. Androgen levels at the high end of the normal range of variation during pregnancy (Grimshaw, Sitarennios, and Finegan, 1995) and androgens produced by a male twin (Cole-Harding, Morstad, and Wilson, 1988) both lead to greater spatial abilities in girls. Abnormally high androgen levels produced by congenital adrenal hyperplasia (CAH) produce enhanced spatial abilities in girls (Hampson, Rovet, and Altmann, 1998) and adolescent women (Resnick et al., 1986). In adults, exogenous testosterone also can produce improved spatial abilities. Therapeutic administration of testosterone to adult transsexuals (Van Goozen et al., 1995) and to men aged 60 to 75 years (Janowsky, Oviatt, and Orwoll, 1994) both produced improved spatial abilities. All these data sources clearly indicate an effect of male hormones, as predicted by the sexual selection hypotheses.

The foraging hypotheses make no predictions about the pattern spatial abilities should show across the life span or how hormonal variation might influence the occurrence of a sex difference in human spatial abilities. Without additional assumptions about age-related changes in the division of labor for foraging or endocrine effects on foraging, the absence of any specific predictions for the foraging hypotheses means that they are unable to account for existing data on hormonal effects on the sex difference in human spatial abilities.

The dispersal hypothesis, as noted previously, predicts greater spatial ability in women than in men. It predicts that this female superiority should emerge in the late juvenile or early adult period, and if followed strictly, predicts that there may be little sex difference in human spatial ability after the dispersal phase. This hypothesis clearly is contradicted by the nature of the sex difference in human spatial ability and by data on hormonal effects on spatial ability.

The fertility and reproduction hypothesis holds that the sex difference in human spatial ability is due in part to selection against a large home range in women during the reproductive years. Its predictions are that emergence of the sex difference should coincide with puberty in girls and that pregnancy should have an inhibitory effect on spatial ability. There is some indication that range size is reduced in women during pregnancy (English and Hitchcock, 1968). In addition, spatial ability has been reported to decrease in women during pregnancy, when estrogen levels are high, then return to

normal after delivery (Woodfield, 1984). Estrogen levels also fluctuate during the menstrual cycle, and a number of studies have shown that spatial ability in women is reduced during the high estrogen phase of the menstrual cycle (Komnenich et al., 1978; Hampson and Kimura, 1988; Hampson, 1990; Silverman and Phillips, 1993), although not all studies show this effect (Gordon and Lee, 1993). The interpretation of these results is not that variation in spatial ability across the menstrual cycle is necessarily adaptive, but rather that the effects of estrogen, which are adaptive during pregnancy, depress spatial ability during the menstrual cycle, too. These results, along with the indication of early pubertal onset of sex differences in spatial ability, are as predicted by the fertility and parental care hypothesis.

Hormonal effects on human spatial ability thus show an enhancing effect of testosterone on male spatial ability, as expected if sexual selection on males contributed to the evolution of a sex difference in human spatial ability, and also an inhibitory effect of estrogen on female spatial ability, as expected if natural selection for fertility and reproduction contributed to the evolution of this sex difference. As noted earlier, increased spatial ability in males and decreased spatial ability in females both are found during breeding in other mammals.

That the contemporary functioning of our cognitive apparatus bears the traces of our evolutionary past should not be surprising. On an evolutionary time scale, we have only very recently left our environment of evolutionary adaptedness. Lingering sex differences in spatial ability are a consequence of adaptation to this environment and the ecological problems it presented. Their existence encourages us to ask evolutionary questions about other aspects of cognitive organization and perhaps begin to understand more generally the adaptations that are human cognition.

ACKNOWLEDGMENTS The author thanks Amy Gordon, Elizabeth Hampson, John Tooby, and Leda Cosmides for their many helpful comments on the manuscript. Preparation of this chapter and the author's research are supported by grants from the Natural Sciences and Engineering Research Council of Canada.

84 What's Human about the Human Brain?

TODD M. PREUSS

ABSTRACT Understanding how human brain organization differs from that of other species is essential for understanding the neural bases of human cognitive and behavioral specializations. Nevertheless, neuroscientists have largely ignored this subject. A review of the small body of available evidence indicates that the human brain became enormously enlarged following the divergence of humans from African apes, with association cortex expanding disproportionately. There is, however, no evidence that humans evolved new cortical areas; indeed, a reasonable case can be made that classical language areas have homologs in nonhuman primates. Humans possess morphological characteristics (sylvian-fissure asymmetries) and features of cortical histology that monkeys lack, although apes are more similar to humans in these respects. We can improve our understanding of human brain specializations by directly comparing humans, apes, and other nonhuman primates using the wide array of available morphological and histological techniques that do not require invasive or terminal procedures.

Homo sapiens: The undiscovered primate

Given what we know about the human brain, two facts stand out as astonishing: (1) We know very little about what distinguishes the human brain from that of other species; and (2) apparently, few neuroscientists regard fact 1 as much of a problem. To be sure, we know a great deal about mammalian and primate brains generally; we also know quite a bit about the localization of function in the human brain, thanks to recent developments in imaging technology. Nonetheless, neuroscientists have devoted little effort to identifying the distinctively human features of the human brain. As a result, no well-developed theory of human mind–brain organization exists—not one that takes the distinctive characteristics of the human brain into account and explains how and why human cognition is different from that of, say, rhesus monkeys. To put the matter bluntly, cognitive neuroscience has very little to say about the specifically human aspects of human nature.

Why are we so ignorant about something so fundamental? This chapter considers the practical and theoretical difficulties posed by the study of human brain specializations, surveys the evidence regarding some

proposed human brain specializations, and discusses some prospects for future discovery. One of the principal lessons of this review is that our ignorance of human brain specializations has more to do with prevailing (and erroneous) ideas about the nature of brain evolution than with the inherent difficulty of studying it.

Identifying human brain specializations

Is it even possible to study human brain specializations? At first glance, the task appears to entail insuperable difficulties. For one thing, there is relatively little we can learn about brain evolution from the study of fossils. Although fossils provide evidence about evolutionary changes in brain size and external morphology, fossils do not preserve information about the histology or internal organization of the brain. But the lack of fossils does not preclude an evolutionary analysis of internal brain structure. Molecular biologists are able, through comparative studies of living species, to reconstruct the evolutionary history of genomes in remarkable detail. To do so, they employ the standard “cladistic” techniques of modern evolutionary biology (Harvey and Pagel, 1991), an approach that can be applied to brain evolution as well (Nishikawa, 1997; Preuss, 1993; Preuss and Kaas, 1996).

It is difficult to overstate the importance of comparative studies—patently, one cannot understand human brain specializations simply by studying humans. Humans share many features of brain organization with other primate and mammalian species by virtue of common ancestry; but while these shared features are, without doubt, important in the functional economy of the human brain, they are not *distinctively* human. Our knowledge of the human brain may advance significantly as the result of, say, advances in imaging technology; however, we cannot enhance our knowledge of what is distinctively human about the human brain unless we can specify what it is humans possess that other species lack, and what other species possess that humans lack (Preuss, 1995a). Thus, from the perspective of cognitive neuroscience, understanding what it is to be human requires comparing human brains to those of other species.

Scientists seeking to undertake these comparisons encounter some genuine technical hurdles, however. As

TODD M. PREUSS Institute of Cognitive Science, University of Southwestern Louisiana—New Iberia Research Center, New Iberia, La.

Crick and Jones (1993) note, studies of human beings face technical limitations not encountered in studies of laboratory animal species. The most informative techniques available for tracing neural connections and studying neuronal activity require invasive and terminal experimental procedures. These techniques are, of course, unsuitable for use in humans. On the other hand, most modern human studies employ noninvasive imaging technologies. These provide much information about the localization of function in the brain and about cerebral morphology (the sizes of brain structures, patterns of cortical folding, etc.), but they tell us little about the connections or intrinsic organization of brain structures. Furthermore, scanning technologies are difficult to adapt for use with nonhuman species, especially in paradigms that involve behaving subjects. Thus, for the present at least, the noninvasive methods used to study humans and the invasive methods used to study laboratory animals provide us with different kinds of information.

Although this methodological gap is real, its magnitude should not be overstated. One can certainly use a variety of techniques to compare the cerebral morphology of humans and nonhuman species (Semendeferi et al., 1998; Zilles et al., 1996). Finer levels of organization can be investigated as well. The past two decades have seen the development of new histological techniques, including immunocytochemical, autoradiographic, and related procedures; and a fantastic array of antibodies and other ligands is now available for probing nervous system organization. With these tools, one can localize neurotransmitters and receptors, structural molecules (e.g., neurofilaments and microtubules), extracellular matrix components, calcium-binding proteins (e.g., calbindin and parvalbumin), and enzymes (e.g., acetylcholinesterase and cytochrome oxidase). One signal virtue of these techniques is that they can be used effectively with autopsied brain tissue from humans as well as from nonhuman species; they are therefore well suited for comprehensive comparative studies involving humans. Although current post-mortem histological techniques do not allow one to study long connections within the brain, they do make it possible to study aspects of laminar, modular, and cellular organization of the cortex in great detail. Also, because cortical areas differ in the density and laminar distribution of particular molecules, histochemical techniques can be used to map the location and extent of cortical areas, supplementing the classical cyto- and myeloarchitectonic techniques. Increasingly, these techniques are being applied to the study of the human brain, as well as to those of nonhuman species. Thus, even as we look forward to improvements in technique that will make it possible to do comparative, in

vivo studies of connectivity (Paus et al., 1997) and functional localization (Takechi et al., 1997), we already possess the means to carry out highly informative comparisons of human and nonhuman brains.

Continuity versus diversity in cerebral evolution

If we do not lack the means to study human brain specializations, why do we know so little about them? The answer, I believe, lies in the continuing influence of outdated ideas about brain evolution. Neuroscientists, as a group, hold firmly to the view that mammalian species differ little in internal brain organization, the main differences being matters of size. If one accepts this premise, the only specialization of the human brain worth considering is its peculiar size—human brains average about three times the volume of chimpanzee brains (Stephan, Baron, and Frahm, 1988), chimpanzees being our closest relatives and also quite similar to us in body size.

This emphasis on the *continuity* of brain organization across mammals has an impeccable lineage, deriving as it does from Charles Darwin. Darwin claimed that “the difference in mind between man and the higher animals, great as it is, is certainly one of degree and not of kind” (Darwin, 1871, p. 105). For Darwin, humans were essentially big-brained apes, greatly improved in intelligence and morals, perhaps, but not different in fundamental ways. T. H. Huxley, who was Darwin’s ally and a neuroanatomical authority, specifically denied that humans possess features of brain organization that other primates lack (Huxley, 1863). Indeed, early Darwinians and anti-Darwinians both believed the theory of evolution by natural selection would be disproved if humans could be shown to possess unique features of brain organization (Preuss, 1993; Richards, 1987).

In keeping with Darwin’s views, subsequent generations of psychologists and neuroscientists have typically emphasized the similarities between animal species and downplayed the differences (for historical reviews, see Povinelli, 1993; Preuss, 1993, 1995a; Preuss and Kaas, 1998). In psychology, for example, the doctrine of behaviorism held that vertebrate behavior was to be explained by reference to a small set of learning processes common to all species (Boakes, 1984). At the same time, neuroscientists such as the influential Karl Lashley (Lashley, 1949) were championing the view that the only important brain difference between species was size. Similarly, among modern neuroscientists it has been claimed that there is a “basic uniformity” of cortical organization among mammals, as Rockel, Hiorns, and Powell (1980) put it, a claim that has found much favor (e.g., Creutzfeldt, 1977; Eccles, 1984; Mountcastle,

1978; Phillips, Zeki, and Barlow, 1983; Szentágothai, 1975). The core idea is that the cortex is a collection of narrow, vertical cell columns, consisting of a specific complement of pyramidal cells and interneurons that span the six layers of cortex, these columns being interconnected in stereotyped ways. Columns are considered to be a fundamental information-processing unit of cortex and, given their supposedly stereotyped organization, perform the same transformation on incoming information, no matter what their location in the cortex. According to this view, evolution modifies brain structure mainly by adding new columns, while conserving column structure.

For neuroscientists, there are good reasons to hope that the doctrine of continuity is true. With its Darwinian imprimatur, it would seem to be on sound evolutionary footing. Moreover, it is compatible with the popular idea that living forms can be arranged along a phylogenetic scale, with us, the big-brained humans, at the top, the crowning achievement of evolution. At the same time, the doctrine of continuity affirms the qualitative similarity of animals. Thus we can regard rats and rhesus monkeys as simplified models of human beings, without having to worry about whether humans have evolved brain specializations those animals lack or, worse, whether rats and rhesus monkeys have specializations that humans lack.

The appeal of continuity notwithstanding, it is important to recognize that modern evolutionary biology has abandoned this part of Darwin's doctrine. Evolutionists are no longer troubled by the idea that a given species may possess structures that its close relatives lack; it is acknowledged, for example, that humans possess structures of the hands and feet that apes lack (Aiello and Dean, 1990). Furthermore, evolutionists today regard phylogeny as primarily a matter of diversification rather than ascent or progress (see especially Bowler, 1996, and Richards, 1987, 1992, for historical reviews). As a consequence, they have adopted the branching tree as the appropriate metaphor for evolution and have dispensed with the phylogenetic scale. These changes of perspective have profoundly affected the evolutionary view of humanity's place in nature: Whereas evolutionists once regarded humans as the near-inevitable product of a general evolutionary progression from the simplest to increasingly complex forms, today they regard the human species not as the apogee of evolution, but rather as one remarkable evolutionary outcome among many (figure 84.1).

Taking the modern view of evolution seriously, we should expect that mammals exhibit diverse psychological organizations. Under behaviorism, with its emphasis on just one or two basic learning processes, it is difficult

to imagine how animals could evolve different psychologies. By contrast, modern cognitive science conceives the mind as a collection of specialized component processes; under this view, one can envision a diversity of minds, with species varying both in the cognitive processes they possess and in the interactions among those processes. Psychologists are now exploring how species differ in cognitive organization, and have begun to characterize the distinctive features of human cognition and behavior. Proposed human specializations include language (Tomasello and Call, 1997; Wallman, 1992), a strong population bias for left-hemisphere dominance for upper-limb control (i.e., right-handedness; McGrew and Marchant, 1997), and "theory of mind"—the propensity to interpret behavior by making inferences about mental states, rather than merely in terms of behavioral tendencies (Cheney and Seyfarth, 1990; Povinelli and Eddy, 1996; Povinelli and Preuss, 1995; Tomasello and Call, 1997). There are likely to be many additional human-specific cognitive characteristics.

If psychological organization varies across species, we should not be surprised to discover that brain organization varies as well. Indeed, there are now so many well-documented examples of nontrivial variations in mammalian brain structure—and especially in cortical organization—that the concept of "basic uniformity" has become untenable (Preuss, 1993, 1995a,b; Preuss and Kaas, 1998). Diversity is exhibited in many dimensions of cortical organization. The cell biology of the cortex is variable, with species exhibiting distinctive differences in the morphologies and biochemical phenotypes of pyramidal cells and interneurons (Brückner et al., 1994; Garey, Winkelmann, and Brauer, 1985; Glezer et al., 1993). Individual areas, such as the primary visual area (V1), exhibit species variations in the laminar distribution of thalamic afferents and in the connections between layers (reviewed by Casagrande and Kaas, 1994; Kaas and Preuss, 1993). There are also marked differences between mammalian groups in the laminar distribution of neurotransmitters and receptors within homologous areas (Berger and Gaspar, 1995; Gebhard et al., 1995). The manner in which areas are parceled into subdivisions can also vary dramatically. For instance, area V1 of primates is characterized by the presence of small, repeating territories of high metabolic activity in the upper layers of cortex. These are known as "blobs" (Horton and Hubel, 1981). Although blobs are also present in carnivores, they are absent in animals thought to be closely related to primates (tree shrews and bats) and many other mammals as well, suggesting that blobs evolved independently in primates and carnivores (Preuss and Kaas, 1996). Finally, the number of major structural subdivisions (areas) of the cortex differs

A

B

FIGURE 84.1 (A) Early views of human evolution, such as those of G. Elliot Smith (1924), a pioneering neuroanatomist and primatologist, depicted humans as the centerpiece of evolution. The path to humans is straight upward, while other species are set off on side branches. The Old World and New World monkeys are drawn as though they stopped evolving millions of years ago! (B) Modern views of human evolution depict humans as one of many diverse outcomes of primate evolution. The lower part of B shows the evolutionary relationships among living primate groups, as currently understood; the upper part expands the portion of the primate tree that contains the African ape group (gorillas, chimpanzees, and humans). The rich fossil record of human evolution indicates that modern humans are the survivors of what was once a remarkable radiation of human-like (hominid) primates. Comparative molecular and anatomical evidence indicates that humans are very closely related to the living African apes, the chimpanzees and gorilla, and chimpanzees are probably the closest relatives of humans. Humans are more distantly related to orangutans and gibbons, the other members of the ape-human superfamily (Hominoidea). Humans are even more distantly related to Old World monkeys, which include the familiar macaque monkeys (genus *Macaca*). As this diagram suggests, the fossil record of African ape evolution is extremely poor compared to the wealth of the hominid record. (Principal sources: Strait, Grine, and Moniz, 1997; Wood, 1996.)

among mammals. There appears to be a small set of areas (perhaps 20 or so) that are widely shared among extant mammals—and probably among ancestral mammals—but some mammalian groups have many more areas than others (Allman, 1990; Northcutt and Kaas, 1995). Primates and carnivores, for instance, have independently evolved many higher-order visual areas (Kaas and Krubitzer, 1991), and anthropoid primates possess dorsolateral prefrontal areas (and related connectional systems) that are not found in other mammals (Preuss, 1995b; Preuss and Goldman-Rakic, 1991a,b).

It is clear that evolution of mammalian brains was marked not only by changes in size, but by diversification of structure as well. It thus makes sense for neuroscientists to seek to identify the constellation of brain characteristics that are distinctive of particular mammalian lineages, including the human lineage. But, as the following section makes clear, much work remains to be done before we will have a detailed account of distinctively human brain systems.

Possible human brain specializations

In this section we consider current evidence pertaining to the ways human brain organization differs from that of other primates, particularly apes, our closest relatives, and Old World monkeys, the animals most closely related to the ape-human (hominoid) group (figure 84.1). In addition to the unusually great size of the human

brain, candidate human specializations include the differential enlargement of specific brain regions (namely the frontal lobe, association cortex, and portions of the cerebellum), the addition of new cortical areas, a unique pattern of cerebral asymmetries, and modifications of the cellular and connectional organization of the cortex.

ENLARGED ASSOCIATION CORTEX Enlargement of the cerebral cortex accounts for most of the difference in brain volume between humans and other primates (Stephan, Frahm, and Baron, 1981). But was the evolutionary enlargement of human cerebral cortex a general enlargement, or did it entail the differential expansion of specific regions? Many have concluded that there was an expansion of specific cortical regions, notably the classical “association” regions of the parietal, temporal, and frontal lobes (e.g., Blinkov and Glezer, 1968; Brodmann, 1909, 1912; Elliot Smith, 1924; Le Gros Clark, 1959).

Frontal cortex has been singled out for special attention (for reviews, see Falk, 1992; Semendeferi et al., 1997). There are sound reasons for thinking that the frontal cortex was extensively modified during human evolution, given its role in language and evidence of its involvement in theory of mind (e.g., Fletcher et al., 1995). Based on his quantitative, comparative studies of the cortical mantle in primates, Brodmann (1912) maintained that one segment of the frontal cortex in particular, the prefrontal cortex (“Regio frontalis,” in his terminology), underwent progressive evolution, being larger in apes than in monkeys, and larger in humans than in apes (figure 84.2). Blinkov and Glezer (1968) provided evidence that both the prefrontal cortex and the frontal cortex as a whole were enlarged in human evolution relative to posterior cortex.

Enlargement of frontal or prefrontal cortex in human evolution has not been universally accepted, however (see the review of Semendeferi et al., 1997). Semendeferi and colleagues, for instance, re-examined the issue, using structural MRI to compare frontal and nonfrontal cortical volumes and surface areas in humans, apes, and monkeys. They concluded that frontal cortex was *not* enlarged in recent human evolution, humans having about the same relative amount of frontal cortex as apes, about 31–37% of total hemispheric volume, although humans might still have more frontal cortex than monkeys (figure 84.2).

Why are there such pronounced discrepancies in published studies of frontal lobe size? Sampling error may contribute to the differences, as all the existing data sets are extremely small, particularly with regard to the number of ape individuals included. Also, different morphometric approaches have been used. Finally,

FIGURE 84.2 The fraction of the cerebral cortex occupied by the prefrontal, frontal, and nonfrontal cortex in humans, apes (chimpanzees, gorillas, orangutans, and gibbons), and Old

World monkeys (macaques and baboons), as indicated by the studies of Brodmann (1912), Blinkov and Glezer (1968), and Semendeferi et al. (1997).

different structures were compared in these studies: Semendeferi and colleagues compared the entire frontal cortex (including prefrontal, precentral, and anterior cingulate cortex) to nonfrontal cortex; Brodmann compared prefrontal cortex (excluding the precentral and anterior cingulate regions) to non-prefrontal cortex; and Blinkov and Glezer considered prefrontal, premotor, and primary motor cortex surface areas as percentages of total cortical surface area.

The distinction between *frontal* cortex and *prefrontal* cortex may be critical in this regard. Even if we accept that the frontal lobes did not expand out of proportion to the rest of the cortex in human evolution, as Semendeferi and associates argue, it does not follow that the percentage of prefrontal cortex remained unchanged. There is, in fact, reason to think that humans possess a relatively large amount of higher-order frontal and posterior association cortex. In addition to the direct morphometric evidence for association cortex enlargement offered by Brodmann (1912) and Blinkov and Glezer (1968), there is substantial indirect evidence as well. Although human brains are about three times the volume

of great ape brains, the absolute amounts of cortex devoted to the primary visual area (Blinkov and Glezer, 1968; Frahm, Stephan, and Baron, 1984) and the primary motor area (Blinkov and Glezer, 1968) are similar in humans and apes. Consistent with this, we recently found that humans and chimpanzees differ in the location of primary motor cortex (area 4) with respect to cortical sulci: In humans, area 4 is largely confined to the anterior bank of the central sulcus; but in chimpanzees, area 4 occupies the anterior bank of the central sulcus, the precentral gyrus, and most of the precentral sulcus as well (Preuss et al., 1997a). Therefore, motor cortex probably occupies a smaller fraction of frontal cortex in humans than in chimpanzees, implying an expansion of premotor and/or prefrontal cortex in human evolution. Likewise, the primary visual area and other lower-order visual areas appear to have been displaced posteriorly in humans compared to other primates (Tootell et al., 1996; Ungerleider and Haxby, 1994), suggesting an expansion of posterior association cortex. Armstrong's comparative studies of thalamic nuclei (summarized in Armstrong, 1982) also provide evidence of the differential enlarge-

ment of human association cortex. Armstrong found that the thalamic nuclei that project to primary visual and auditory cortex (i.e., the lateral and medial geniculate nuclei) contain similar numbers of neurons in great apes and humans, whereas nuclei that project to the prefrontal, parietal, and temporal association cortex (including the mediodorsal nucleus and the pulvinar) contain approximately 2–3 times as many cells in humans as in great apes. In sum, the existing data clearly support the view that prefrontal cortex, and posterior association cortex as well, expanded differentially during human evolution.

ENLARGED CEREBELLUM There is no reason to expect that evolutionary changes have been restricted to the forebrain; indeed, there is evidence suggesting that the cerebellum was modified in ape and human evolution. Specifically, ape cerebella are relatively large for primates of their body size, and the human cerebellum is larger still (Passingham, 1975; Stephan, Baron, and Frahm, 1988). There is also evidence that one division of the deep cerebellar nuclei in particular, the dentate nucleus, is larger relative to body weight and hindbrain volume in humans than in apes (Matano and Hirasaki, 1997). The dentate receives projections from the lateral cerebellar cortex, and projects in turn to the cerebral cortex via the thalamus. Leiner, Leiner, and Dow (1986) argue that apes and humans possess a unique subdivision of the dentate that sends outputs to the prefrontal cortex (via the thalamus). These considerations are particularly interesting in view of the accumulating evidence that the cerebellum contributes to cognitive as well as motor functions (Ivry and Baldo, 1992; Leiner, Leiner, and Dow, 1986; Middleton and Strick, 1994; Schmahmann, 1991). Leiner and colleagues (1986), for example, argue that the cerebellum contributes to the routinization of complex cognitive procedures and hence to mental agility. If the emergence of higher-order representations depends on the routinization and consolidation of lower-order schemas, as posited by Karmiloff-Smith (1992), interactions between the cerebellum and cerebral cortex could play an important role in the development of higher-order cognitive representations.

NEW CORTICAL AREAS How has the organization of human cerebral cortex been modified during its evolutionary expansion? One very appealing possibility is that new areal subdivisions evolved. In mammals, there appears to be a relationship between brain size and number of cortical areas, such that larger-brained taxa tend to have more areas than smaller-brained forms (Allman, 1990; Brodmann, 1909; Kaas, 1987; Preuss and

Kaas, 1998). The expectation that humans possess new cortical areas becomes even stronger if one believes that the existence of human-specific psychological capacities, such as language or theory of mind, implies the existence of human-specific processing “modules,” because we can readily cast cortical areas in the role of psychological modules. In this vein, it has been suggested that Broca’s area and other language-related cortical regions are probably unique to humans (e.g., Brodmann, 1909; Crick and Jones, 1993; Killackey, 1995).

However appealing this picture, there is at present no good evidence that humans possess cortical areas in addition to those found in other primates (figure 84.3). Several recent frontal-lobe studies bear on this point. Petrides and Pandya (1994) concluded there is essentially a one-to-one match between the cytoarchitectonic areas of macaque frontal cortex and that of humans. Similarly, recent architectonic studies of human dorso-lateral prefrontal cortex (Rajkowska and Goldman-Rakic, 1995) and dorsomedial premotor cortex (Baleydier, Achache, and Froment, 1997; Zilles et al., 1995) have identified areas known to be present in macaques, but not additional, human-specific areas.

It would be premature, nonetheless, to conclude that humans have exactly the same complement of frontal areas that macaques and other nonhuman primates have. Our understanding of cortical areal organization is far from complete, even in macaques, the primates about which we know most. The widely used architectonic maps of Brodmann (1909) and Walker (1940) certainly understate the number of frontal lobe areas in Old World monkeys: Areas unrecognized by these authors have recently been described in the dorsolateral, orbital, and medial prefrontal cortex of macaques (Carmichael and Price, 1994; Petrides and Pandya, 1994; Preuss and Goldman-Rakic, 1989, 1991a,b). Even the primary motor “area” can be subdivided in macaques based on variations in the distribution of neurofilaments (Preuss et al., 1997b). Nor is frontal cortex exceptional: The parcellation of the much-studied visual cortex in Old World and New World monkeys is still not fully settled (Kaas, 1993). Moreover, studies of *human* cortical parcellation are just beginning. Until we have relatively complete and accurate parcellations of the cortex of humans and other primate species, we will not be able to confidently conclude whether humans do or do not possess human-specific cortical areas.

ARE THERE NONHUMAN HOMOLOGS OF HUMAN LANGUAGE AREAS? If we cannot resolve the general question of at least whether humans possess new cortical areas at present, we can at least address the more limited question of whether the language areas are unique to

Brodmann (1909)

Petrides and Pandya (1994)

FIGURE 84.3 The frontal lobe areas of humans (*Homo*) and Old World monkeys (*Cercopithecus* and *Macaca*) according to the cytoarchitectonic studies of Brodmann (1909) and Petrides and Pandya (1994). Brodmann concluded that the number of

areas in the cerebral cortex increased during human evolution, whereas Petrides and Pandya depict humans and macaques as having the same complement of frontal-lobe areas.

humans. If new functions require new cortical areas, and if language is a uniquely human function, then cortical areas specialized for language processing should indeed be found only in humans. Nonetheless, there are long-standing claims that homologs of both Broca's area and Wernicke's area are present in macaques and other non-human primates (figure 84.4).

Most interest has focused on Broca's area, which is usually identified with architectonic areas 44 and 45 of Brodmann (1909). While Brodmann indicated that these areas are unique to humans, others have identified architectonically similar areas in the ventral premotor region of nonhuman primates (see especially Bonin, 1944, and Bucy, 1944). Furthermore, electrical stimulation of the

FIGURE 84.4 Human language areas and their suggested homologs in macaques, based on architectonic and functional similarities. Broca's area in humans is located in the posterior part of the third frontal gyrus (F3), and includes two smaller gyri, pars opercularis (PO) and pars triangularis (PTri). These small gyri are occupied by areas 44 and 45 of Brodmann, respectively. In macaques, the ventral limb of the arcuate sulcus (AS) contains cortex that resembles human areas 44 and 45 ar-

chitectonically. Wernicke's area has been identified with architectonic area Tpt in humans, and there is a similar area in macaques. The cortex of the human supramarginal gyrus (SMG; Brodmann's area 40), which may be involved in language processing, resembles area 7b of macaques. Additional abbreviations: CS, central sulcus; LS, lateral sulcus; SF, sylvian fissure; RF, Rolandic fissure.

ventral premotor region in nonhuman primates produces oral and laryngeal movements (for review, see Stepniewska, Preuss, and Kaas, 1993). Many workers have therefore concluded that a portion of the ventral premotor region of nonhuman primates contains cortex homologous to Broca's area (e.g., Abbs, 1986; Bonin, 1944; Bucy, 1944; Deacon, 1992; Galaburda and Pandya, 1982; Jürgens, 1979; Lieberman, 1985).

Recent studies of ventral premotor cortex in nonhuman primates and Broca's area in humans provide additional evidence of homology (for discussion, see Preuss, 1995a; Preuss, Stepniewska, and Kaas, 1996; Stepniewska, Preuss, and Kaas, 1993). In nonhuman primates, it has been found that ventral premotor cortex represents hand movements as well as orofacial movements. In humans, likewise, the cortex of Broca's area is activated by simple movements of the hands and mouth, as well as during language tasks (Colebatch et al., 1991; Petersen et al., 1988). Rizzolatti, Gallese, and colleagues also suggest that neurons in the anterior ventral premotor cortex of macaques have properties suited for the analysis of orofacial and manual gesture, and propose that this area is preadapted for a role in language (Gallese et al., 1996; Rizzolatti et al., 1996).

Homologs of posterior language cortex—specifically Wernicke's area and the inferior parietal cortex (supramarginal and angular gyri)—may also exist in nonhuman primates (see figure 84.4). For example, Galaburda and Pandya (1982) have argued that macaques possess a cytoarchitectonic zone, area Tpt in the temporal cortex of

the posterior sylvian fissure that resembles Wernicke's area in architecture and location. Eidelberg and Galaburda (1984) also note the architectonic similarity of the inferior parietal cortex of humans and nonhuman primates (area PG; angular gyrus). Functional imaging studies provide additional evidence for homology between the supramarginal gyrus of humans (Brodmann's area 40) and the anterior inferior parietal lobule (anterior area 7) of nonhuman primates. In nonhuman primates, anterior area 7 is known to represent the face and forelimb (Leinonen et al., 1979). In humans, the supramarginal gyrus is activated during linguistic tasks (Paulescu, Frith, and Frackowiak, 1993), but also during nonlinguistic forelimb movements (Colebatch et al., 1991). It is noteworthy that in macaques, the anterior parietal cortex, ventral premotor cortex, several somatic areas in the operculum and insula, and at least two ventral prefrontal areas are all interconnected (Preuss and Goldman-Rakic, 1989). Preuss and Goldman-Rakic (1989) proposed that these areas constitute a network of perisylvian somatic areas, representing preferentially the face and forelimb.

If nonhuman primates possess homologs of at least some of the major language-related cortical areas of humans, then we must consider the possibility that human-specific language functions evolved, not by the addition of new cortical areas, but by the modification of pre-existing structures and systems, as Bonin (1944) suggested long ago. Under this view, nonhuman primates possess areas and connectional systems that are preadapted for

FIGURE 84.5 The left and right temporal lobes of humans are remarkably asymmetrical. The figure on the left shows a brain sectioned in the horizontal plane to reveal the superior aspect of the temporal lobes; anterior is to the top. (The cut surface of the cortex is represented by the dark gray fill.) The planum temporale (PT) is larger in the left hemisphere than the right in most people; in this individual, the right PT is scarcely evident.

H₁ and H₂ are components of Heschl's gyrus, which corresponds to the primary auditory area. The figures on the right illustrate the asymmetry in the course of the sylvian fissure. In most individuals, the sylvian fissure is longer and flatter in the left hemisphere than in the right. (Figures are based on photographs in Galaburda, 1984.)

language, with functions that make them suitable for “recruitment,” as Bonin put it, by language (see also Gallese et al., 1996; Kimura, 1976, 1993; Lieberman, 1985; Rizolatti et al., 1996). It is intriguing that the perisylvian areas represent forelimb as well as orofacial function, for this may explain why humans can so readily acquire a manual sign language when deafness renders the auditory-verbal channel unavailable (Preuss, 1995a). It may also be germane to the many evolutionary scenarios of language origins that hold that humans passed through an evolutionary stage in which manual gesture was a far more important component of communication than it is in modern humans (Hewes, 1976).

Although one can make a reasonable case that homologs of human language areas exist in nonhuman primates, we probably should not regard the matter as settled. Until we have accurate charts of cortical areas in humans and other primates, and a very detailed mapping of the distribution of linguistic and nonlinguistic functions in the human perisylvian cortex, we cannot rule out the possibility that language is represented in areas adjacent to, but distinct from, the areas representing nonlinguistic functions. Nevertheless, it must be empha-

sized that there is currently no strong evidence that the classical language areas are unique to humans.

UNIQUE CEREBRAL ASYMMETRIES The fact that the human left hemisphere is dominant for language and upper-limb control in most individuals suggests that the hemispheres should be structurally asymmetrical, and indeed they are. The region of temporal cortex usually identified with Wernicke's area—the so-called planum temporale, the posterior part of the temporal lobe buried within the sylvian fissure—is highly asymmetrical (figure 84.5). Geschwind and Levitsky (1968) reported that the left planum temporale was larger than the right in 65% of human brains examined, the remainder being about equal or larger on the right. Furthermore, the external appearance of the sylvian fissure shows marked asymmetry in a majority of individuals, the right sulcus being shorter than the left and showing a distinct upward bend at its posterior end (Foundas, Leonard, and Heilman, 1995; LeMay and Culebras, 1972) (figure 84.5). Broca's area, which corresponds to the posterior part of the third frontal convolution and includes gyri known as pars triangularis and pars opercularis, is also

asymmetrical. Specifically, the sulci within Broca's region are deeper and longer on the left than on the right (Albanese et al., 1989; Falzi, Perrone, and Vignolo, 1982; Foundas et al., 1996; Foundas, Leonard, and Heilman, 1995), suggesting that the amount of cortex is greater on the left than the right. Consistent with this is a report that cytoarchitectonic area 44, which occupies pars triangularis, is larger on the left than the right (Galaburda, 1980). Cortical area Tpt within Wernicke's region is also reported to be larger on the left (Galaburda and Sanides, 1980). Finally, there are reports of left-right asymmetries of pyramidal cell size and dendritic morphology in the classical language regions (Hayes and Lewis, 1995; Hutsler and Gazzaniga, 1996; Scheibel et al., 1985).

Given that humans are distinctive among primates in their possession of language (which is localized mainly in the left hemisphere in most individuals) and in their preference for the right hand (control of which is localized in the left hemisphere in most persons), it is reasonable to suppose that the constellation of left-right perisylvian asymmetries is unique to humans. It is reported, however, that nonhuman primates possess at least some of the asymmetries found in humans. Asymmetries of sylvian fissure length (with the left longer than the right) are present in Old World monkeys and apes as well as in humans (see the review of Bradshaw and Rogers, 1993). Furthermore, in apes, but not monkeys, the tip of the sylvian fissure is usually higher on the right than on the left, as is the case in humans (LeMay and Geschwind, 1975; Yeni-Komshian and Benson, 1976). Finally, there are reports that chimpanzees possess planum temporale asymmetries similar to those of humans (Gannon et al., 1998; Hopkins et al., 1998). Thus, on current evidence, the pattern of asymmetries of the posterior sylvian fissure appears to be qualitatively similar in apes and humans. It remains possible that there are differences between apes and humans in the degree of fissural asymmetry (Yeni-Komshian and Benson, 1976) or differences in the cellular organization of language-related regions; these possibilities have not yet been adequately addressed empirically. The presence of human-like asymmetries in the posterior sylvian fissure of apes, which lack language and handedness, implies that there is no simple relationship between cerebral asymmetries and cognitive and hemispheric dominance for language and upper-limb control in humans (Gannon et al., 1998).

CHANGES AT FINER LEVELS OF ORGANIZATION
To date, relatively little attention has been paid to the possibility that humans differ from other primates in the cellular and laminar organization of the cortex. Given the lack of evidence for human-specific cortical areas,

and the rapidly accumulating evidence of phyletic diversity in cortical histology, the search for human specializations at finer levels of cortical organization assumes new importance. As already noted, the development of modern histological techniques, especially immunocytochemistry, makes it possible to compare the cortical organization of humans and other species in considerable detail.

One well-documented difference in the cortical histology of macaques and humans concerns the primary visual area, V1 (figure 84.6). In primates, portions of layer IV stain densely for the metabolic enzyme cytochrome oxidase (CO). In macaques and many other Old and New World monkeys, CO staining occurs in two bands, a thick lower band, corresponding to layer IVC, and a thin upper band, corresponding to layer IVA (Horton, 1984). The dense CO staining in these bands presumably reflects the high level of metabolic activity of the terminals of thalamic afferent fibers, which are extremely numerous in layers IVC and IVA. Humans are different. Although they possess a layer IVA, as judged from cytoarchitecture, layer IVA does not stain densely for CO; humans have only a single CO-dense band, corresponding to layer IVC (Horton and Hedley-Whyte, 1984; Wong-Riley et al., 1993). This suggests that there may be fewer thalamic afferents in IVA of humans than in macaques, or that these afferents have lower firing rates (Wong-Riley et al., 1993). Macaques and humans also differ in the distribution of neurons containing the calcium-binding protein, calbindin: Layer IVA has very few calbindin-immunoreactive cells in macaques, but it has a dense population of these cells in humans (Hendry and Carder, 1993). These findings suggest that the pathway from the parvocellular (P) layers of the LGN, which terminates (in part) in layer IVA of primary visual cortex, was modified at some point in human evolution (Preuss, Qi, and Kaas, 1998).

Humans and macaques also differ in the biology of pyramidal cells. Campbell and Morrison (1989) reported that humans possess more pyramidal cells in the superficial cortical layers that express nonphosphorylated neurofilament protein (recognized by the SMI-32 antibody) than do macaques, this difference being evident across a number of cortical areas. It is not known why some pyramidal cells express the nonphosphorylated neurofilament epitope recognized by SMI-32 while others do not. However, these results suggest that the organization of the upper cortical layers of humans may differ in important ways from macaques. One possibility is that humans possess classes of pyramidal cells that are absent in macaques (Campbell and Morrison, 1989). Alternatively, the connectional organization of the superficial layers may be different in humans and

FIGURE 84.6 The laminar organization of the primary visual cortex (area V1 or 17) revealed by staining for cytochrome oxidase (CO). In macaques and other Old World and New World monkeys, there is a distinctive, narrow band of dense CO

staining, corresponding to layer IVA, located above the main band of dense staining in layer IVC. In humans, layer IVA does not stain strongly for CO. Scale bars are 500 μ m.

macaques. The latter suggestion follows from experimental studies in macaques indicating that pyramidal cells that stain for SMI-32 and those that do not project preferentially to different targets (Hof et al., 1996). The higher percentage of SMI-32 immunoreactive cells in humans as compared to macaques suggests that certain classes of corticocortical projections may be stronger in humans than in macaques. In addition to this difference in pyramidal cells, macaques and humans reportedly differ in the biochemistry of their chandelier cells, a class of cortical interneuron (del Río and DeFelipe, 1997).

The aforementioned studies provide evidence of differences in the cellular and laminar organization of macaque and human cortex. These results do not, however, allow us to determine whether the differences represent *human* specializations in the strict sense, or *hominoid* specializations—i.e., derived features that humans share with apes. To address this issue, my collaborators and I have begun a series of studies comparing the cortical histology of humans, chimpanzees (the animals most closely related to humans), and Old World and New World monkeys. Our initial results indicate that the primary visual cortex of chimpanzees resembles that of humans, and differs from those of macaques and other Old World and New World monkeys, in having a layer IVA that stains weakly for CO and contains a dense band of calbindin-immunoreactive cells (Preuss, Qi, and Kaas, 1998). In addition, we have examined the distribution of neurons expressing nonphosphorylated neurofilament in precentral motor cortex, using SMI-32 (Preuss et al., 1997a). Consistent with Campbell and

Morrison (1989), we found that humans have more SMI-32 immunoreactive pyramidal cells in the outer cortical layers than do macaques. Once again, however, we found that chimpanzees are more like humans than like macaques. Thus, in the aspects of cortical histology we have examined so far, the characteristics that distinguish humans from macaques appear to be hominoid specializations rather than true human specializations.

Conclusions

In order to build theory of human brain systems that can account for distinctively human behavioral and cognitive capacities, we need to understand how the human brain differs from that of other species. As the current survey makes clear, we do not yet have a deep understanding of human brain specializations, although we are in a position to draw certain significant conclusions. Humans have disproportionately enlarged association cortex compared to apes and monkeys; it remains an open question whether humans possess more cortical areas than other primates. Human brains are not merely bigger, better monkey brains, however; they display cerebral asymmetries and features of cortical histology that monkeys lack. Apes, which are more closely related to humans than are monkeys, share with humans a number of brain characteristics not present in monkeys. There is, however, no strong evidence that humans possess more cortical areas than other primates, although the evidence against new human areas remains less than compelling.

This review offers lessons for future research. First, identifying human brain specializations requires comparative studies that include apes, and especially chimpanzees, in addition to monkeys. Studies that compare monkeys and humans, but do not include apes, cannot in principle distinguish hominoid (ape-human) specializations from true human specializations. Second, we need much better maps of cortical areal organization both for humans and other primates if we want to determine definitively whether the evolutionary enlargement of human cortex was accompanied by the addition of new areas, by the enlargement of pre-existing areas (and if so, which areas), or by some combination of both. Third, it is evident that neuroscientists have focused too narrowly on the addition of cortical areas as *the* mode of evolutionary change, neglecting possible changes at finer levels of cortical organization.

Perhaps the most important lesson, however, is that it is possible to pursue the study of human brain specializations very profitably with currently available neuroscientific technologies. While the lack of adequate noninvasive techniques for studying connectivity poses a limitation on our understanding of human specializations, there is every reason to go forward with the techniques currently available for studying cerebral morphology and histology.

The main obstacle to understanding what is human about the human brain is not so much technological as ideological. The special appeal of cognitive neuroscience as a scientific enterprise derives from the widely held belief that there is something unusual about the human brain and cognition. Despite this, adherence to the doctrine of continuity and belief in the basic uniformity of cortical organization have led neuroscientists generally to stress the importance of features of brain organization that are shared widely among species, and to downplay the importance of species differences and the kind of research that is necessary to identify them. But what is distinctively human about the human brain is, after all, a species difference. Unless our profession makes a commitment to comparative studies, and most especially to comparative studies of humans and apes, our knowledge of the human brain will be limited to the ways in which humans resemble monkeys and rats. That would be an important contribution, to be sure, but it would leave cognitive neuroscience without much to say about the very subject that makes the enterprise so appealing in the first place.

ACKNOWLEDGMENTS The author would like to thank the section editors, John Tooby and Leda Cosmides, and also Mary Anne Case, Emmanuel Gilessen, Jon Kaas, David Kornack, Daniel Povinelli, and Katerina Semendeferi, for providing crit-

ical comments on early drafts of this manuscript. The author's research is supported by the USL-New Iberia Research Center and by the McDonnell-Pew Program in Cognitive Neuroscience.

85 “Theory of Mind” as a Mechanism of Selective Attention

ALAN M. LESLIE

ABSTRACT A key component of human intelligence is our ability to think about each other’s mental states. This ability provides an interesting challenge for cognitive neuroscience attempts to understand the nature of abstract concepts and how the brain acquires them. Research over the past 15 years has shown that very young children and children of extremely limited intellectual ability can acquire mental state concepts with ease. Children with Kanner’s syndrome have severe difficulty using these concepts, despite relatively great experience and ability. These discoveries have led to the development of the first information processing models of belief-desire reasoning.

The term “theory of mind” was coined by David Premack (Premack and Woodruff, 1978) to refer to our ability to explain, predict, and interpret behavior in terms of mental states, like *wanting*, *believing*, and *pretending*. Because the behavior of complex organisms is a result of their cognitive properties—their perceptions, goals, internal information structures, and so on—it may have been adaptive for our species to develop some sensitivity to these properties. The capacity to attend to mental state properties is probably based on a specialized representational system and is evident even in young children.

The term “theory of mind” is potentially misleading. It might suggest that the child really has a *theory* or that the child has a theory of *mind* as such. Although there are some writers who hold such views (Perner, 1991; Gopnik and Meltzoff, 1997; Gopnik and Wellman, 1995), I assume simply that the child is endowed with a representational system that captures cognitive properties underlying behavior. To better see what is meant by “theory of mind” ability, consider the following scenario (figure 85.1). Sally has a marble that she places in a basket and covers, and then departs. While she is gone, Ann removes the marble from the basket and places it in the box. A child to whom this scenario is presented then is asked to predict where Sally will look for her marble when she returns. To correctly predict Sally’s behavior, it is necessary to take into account both Sally’s desire for the marble and Sally’s belief concerning the location of the marble. In this scenario, Sally’s belief is

rendered false by Ann’s tampering. Therefore, to succeed on this task, the child must attribute to Sally a belief that, from the attributer’s point of view, is false.

There have been two major discoveries concerning the false-belief problem in figure 85.1. First, Wimmer and Perner (1983), using a somewhat more complex version of the task, found that the majority of 6-year-olds already could pass it, whereas Baron-Cohen and associates (1985), using the version depicted, found that the majority of 4-year-olds could succeed. Subsequently, a large number of studies have confirmed this finding: Whether predicting behavior or reporting where Sally thinks the object is, normally developing children typically solve the problem shortly after the fourth birthday. The second major finding is that autistic children typically fail to solve this task despite mental ages (MAs) well in excess of 4 years, whereas other disabled children—for example, those with Down syndrome—can succeed (Baron-Cohen, Leslie, and Frith, 1985). These two findings raise the following deeply challenging problem for the theorist of cognitive development. How is the young brain able to attend to mental states when mental states cannot be

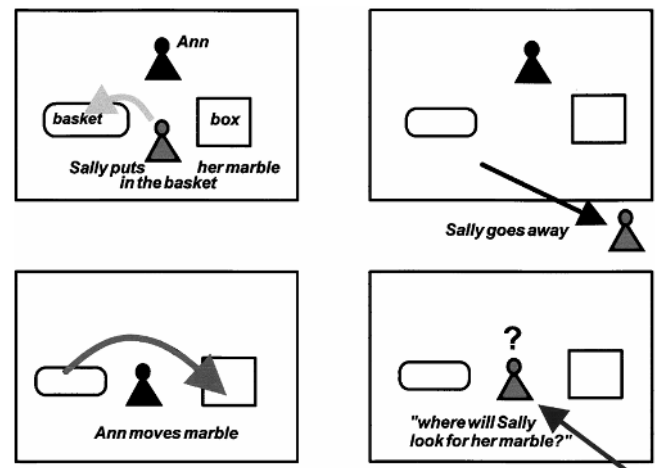

FIGURE 85.1 Illustration of the standard “Sally and Ann” false-belief task given to children to test their ability to attribute beliefs to other people and to calculate the contents of those beliefs correctly. (After Baron-Cohen, Leslie, and Frith, 1985.)

Mother's behavior:

talking to a banana...

Infer mental state:

**mother PRETENDS
(of) the banana (that)
"it is a telephone"**

FIGURE 85.2 The 2-year-old brain can attend to behavior and infer the mental state from which the behavior issues. To do this requires the development of the "M-representation." See this page for further explanation. (After Leslie, 1994.)

seen, heard, or felt? I call this the *fundamental* problem of "theory of mind" because if the child cannot attend to mental states, then how can he or she learn about them?

Previously (Leslie, 1987), I proposed a general answer to the fundamental question of how the young brain can attend to mental states: Attend to behavior and infer the mental state from which the behavior arises. For example, the 2-year-old child watches as mother talks to a banana. If the child were limited to representing simply the mother's behavior then he or she would be unable to recover the significance of the mother's behavior. This he or she can do only by inferring that the mother is pretending that the banana is a telephone (figure 85.2). In fact, 2-year-olds are quite capable of this feat (Harris and Kavanaugh, 1993; Leslie, 1987, 1994).

For the young brain to move attention from behavior to the mental state from which the behavior issues, appropriate processing mechanisms must deploy a system of representation capable of representing mental states. I call this system of representation the *M-representation*, and the associated processing mechanisms the *theory of mind mechanism* (ToMM).

The M-representation provides agent-centered descriptions of behavior using three-place relations that make explicit four kinds of information. The first piece of information specifies the agent involved. The second piece of information identifies an "informational relation" or attitude that the agent holds. The third piece of information identifies an aspect of the world that anchors

the agent's attitude, and the final piece of information identifies the content of the agent's attitude. For example, in the agent-centered description of the mother's behavior shown in figure 85.2, the M-representation shows the agent, **mother**, holding the attitude, **pretends-true**, toward the content, "**it is a telephone**," with regard to the **banana**. The M-representation system is highly flexible. The present example can be extended easily to cover: own pretend play, by having the child process an M-representation which identifies the agent as self (I **pretend-true** of the **banana** "**it is a telephone**"); different mental states, including false beliefs (**mother believes-true** of the **banana** "**it is a telephone**"); different anchors; and different contents. Forming and processing an M-representation requires the brain to integrate information from a number of very different sources.

These ideas led my colleagues and me to develop a neuropsychological perspective on autism, a perspective that also has helped us to understand the normal development of social intelligence (Baron-Cohen, 1995; Frith, Morton, and Leslie, 1991; Happé, 1995; Leslie, 1987, 1991, 1992, 1994; Leslie and German, 1995; Leslie and Roth, 1993; Leslie and Thaiss, 1992; Roth and Leslie, 1998; see also chapter 87). According to the model, the M-representation is deployed by a dedicated processor, ToMM. The ToMM is a specialized component of social intelligence providing the time-pressured, on-line intentional interpretations of behavior that are necessary for an agent to take part effectively in conversations and other real-time social interactions. The ToMM is a mechanism of selective attention, it operates postperceptually, it operates spontaneously whenever an agent's behavior is attended, it is domain specific, and it is subject to dissociable damage. In the limit, the ToMM may be modular. The ToMM employs a proprietary representational system, namely the M-representation. The ToMM is hypothesized to form the specific basis of our capacity to acquire "theory of mind." Finally, the ToMM is damaged in autism (Kanner's syndrome), resulting in the core signs of that neurodevelopmental disorder.

Background assumptions about autism

Autism is a disorder affecting at least 4 or 5 in 10,000 births; approximately 75% of those affected are mentally retarded. The evidence is overwhelming that the disorder has a biological etiology (Gillberg and Coleman, 1992) and is most likely genetic in origin (see chapter 87; also see Bailey et al., 1995).

At present, autism is diagnosed on behavioral grounds, including impaired social skills, language delay, lack of pretend play, and stereotypes, with onset before

36 months of age (American Psychiatric Association, 1994). Large-scale epidemiological studies by Wing and Gould (1979) showed that autistic children suffer a “triad of impairments” relative to nonautistic mentally retarded children matched on mental age. The triad of impairments includes social incompetence, poor verbal and nonverbal communicative skills, and a lack of pretend play. Although approximately 25% of children with autism are not mentally retarded, they still show the “triad of impairments” compared with their peers. This suggests that the triad, although central to the syndrome of autism, is not the result of general mental retardation but reflects a more specific impairment at the cognitive level (Leslie, 1987). Because “theory of mind” abilities underlie human social competence, communication, and pretending, the autistic triad might be the result of an impaired ToMM. These speculations led to the prediction that autistic children would be specifically impaired in their understanding of beliefs in other people.

Investigating the theory of mind mechanism hypothesis: Initial phase

To test the predicted impairment in belief understanding, Baron-Cohen, Leslie, and Frith (1985) studied three groups of children: normally developing 4-year-olds, children with autism, and children with Down syndrome. Subjects were tested on the Sally and Ann false-belief task (figure 85.1). To allow a conservative test of the hypothesis, the autistic children were older (12 years) and thus more experienced than the other two groups (10 years and 4 years) and had a higher mean IQ (82) than the children with Down syndrome (64). After an experimenter explained the scenario with the aid of props, subjects were asked three questions: a Memory question, “In the beginning, where did Sally put her marble?”; a Reality question, “Where is the marble now?”; and a Prediction test question, “Where will Sally look for her marble?”

The results were striking. Eighty-five percent of the normally developing children and 86% of the children with Down syndrome attributed Sally a false belief and predicted that she would look in the basket. Only 20% of the autistic children predicted Sally’s behavior in this way, failing as a group to show their advantage in age, experience, and ability.

Leslie and Frith (1988) replicated these findings with a group of autistic children with mean verbal MAs of 7 years, 2 months, comparing them to MA-matched specific language impaired (SLI) children. All the SLI children passed the task; by contrast, only 28% of the autistic children passed. Leslie and Frith also showed that although autistic children were perfect in a “line of

sight” task, they performed poorly in a test of “seeing leads to knowing.” Perner and associates (1989) investigated a second false-belief task with autistic children. In this task, the child is shown a container for a well-known candy and asked, “What’s in here?” After the child names the candy, the container is opened and the child is shown that it contains only a pencil. The pencil then is replaced and the container again closed. The child is told that when his or her friend comes in, the friend too will be shown the container and asked what is inside. The child then is asked what the friend will say. The results on this task for normally developing children closely follow those obtained from the Sally and Ann task: typically, 3-year-olds fail to predict behavior by attributing a false belief, whereas 4-year-olds typically succeed. Perner and colleagues (1989) found that almost 100% of MA-matched SLI children passed the candies task, whereas 83% of their able autistic group failed.

These initial findings have been replicated and extended by different laboratories around the world (Baron-Cohen, 1995; Mitchell, Saltmarsh, and Russell, 1997; Naito, Komatsu, and Fuke, 1994; Ozonoff, Pennington, and Rogers, 1991; Prior, Dahlstrom, and Squires, 1990; Reed, 1994; Sodian and Frith, 1992; Tager-Flusberg, 1992). Autistic children are impaired in their understanding of beliefs relative to normal developmental milestones, relative to their own level of general intellectual functioning, and relative to other syndromes of mental retardation and language impairment. This pattern is consistent with impairment to their ToMM.

A key question and a key finding

How do we know that the failure of autistic children on false-belief tasks is not due to an impairment in general processing or general reasoning? It is easy to think of nonspecific impairments that would impact on these tasks, for example, impaired working memory, poor executive function, limited abstract reasoning, difficulties with counterfactual reasoning, or other nameless processing factors impaired in critical combinations.

To answer this question, a task that closely parallels the general problem-solving structure of false-belief tasks, but without engaging mental state concepts, would be useful. Zaitchik (1990) devised just such a task, the so-called “photographs” task, in which Sally is downsized, replaced by “hi-tech,” namely a Polaroid camera. Sally’s belief is replaced by a photograph: a mental representation is replaced by a public representation.

Because photographs and other pictures are easily attended to, can be picked up, pointed to, discussed with

mother, and almost always are out of date, they should have a marked advantage in the development of the child over invisible, intangible, immaterial beliefs.

The task begins by ensuring that preschoolers understand the basics of the operation of the camera. After training, the children are asked to take a photograph of a toy cat sitting on a chair (figure 85.3). When the photograph emerges from the camera, the experimenter places it face down on a table. The child does not get to see the photograph; after all, the child did not get to see Sally's belief! The cat then is moved from the chair and placed on the bed. The child is asked the usual control questions, "When you took the photograph, where was the cat? Where is the cat now?" Finally, the child is asked the crucial test question, "In the photograph, where is the cat?"

When Zaitchik gave this task to preschoolers, the results resembled those obtained from the false-belief task: 3-year-olds typically failed, answering the test question with the current location of the cat, whereas 4-year-olds typically passed.

Leslie and Thaiss (1992) adapted this task for use with autistic children and compared their performance with that of normally developing 4-year-olds. Two standard false-belief tasks, the Sally and Ann and candies tasks, were given, along with two photographs tasks—the aforementioned task and a second task in which the photographed object subsequently is replaced with a different object. In this latter task, the test question is, "In the photograph, what is on the chair?" This asks for the identity of an object, as does the test question in the candies task.

The results showed that most of the normally developing 4-year-olds passed both the out-of-date belief tasks and their equivalent out-of-date photograph tasks. Although their performance on the belief and photograph tasks did not differ significantly, for children who passed only one of the tasks, there was a tendency to pass false belief. This tendency also was found by Zaitchik (1990) in her three experiments that allowed the comparison. Together with the pair of tasks from Leslie and Thaiss (1992), these five studies show the same small advantage for out-of-date beliefs over photographs, *using closely parallel task structures*. Experiment-wise, the effect is reliable ($p = .032$), with normally developing children finding false beliefs slightly easier than out-of-date photographs.¹

If only general learning mechanisms are involved, it is surprising that photographs and other pictures are not easier to learn about than beliefs. Moreover, despite attempts to put a brave face on it (Perner, 1995; Leekam and Perner, 1991), these findings are a particular embarrassment for accounts in which the child comes to understand belief by discovering a "theory" about mental states, namely, the theory that "*mental states are represen-*

tations" (Perner, 1991). The failure to find a large advantage for pictures over beliefs supports the idea that something in the young brain compensates for the invisibility of belief. Apparently, if anything, beliefs are easier, not harder, to learn about. This highlights the proposed role of the ToMM as a mechanism that directs attention to otherwise unattendable mental states and thus promotes learning.

The results from the autistic subjects in the study by Leslie and Thaiss (1992) were strikingly different. Autistic children showed their characteristic poor performance on both false-belief tasks coupled with near perfect performance on the equivalent photographs tasks, reversing the pattern found in normally developing children.

Leslie and Thaiss ran a further study in which the camera and photograph were replaced by a "map." Subjects were familiarized with a simple diagrammatic map of a doll's house and were trained in how a puppet, placed on a piece of furniture, could have its position marked on the map with a colored sticker. During testing, the experimenter placed a puppet on the bed and placed a sticker on the map to show where the dog was. Again, the child did not get to see the marked map. The doll then was moved from the bed onto the toy box. After the usual control questions, the child was asked "In the map, where is the doll?" Again, the autistic children fared better on the public representation task than on false belief, whereas the normally developing children showed the opposite pattern.

Figure 85.4 puts these results together. It shows how the autistic children performed with the normal profile on public representation tasks, only with greater success—as *they should*, given their age and ability advantage over the other group. When a belief task enters the comparison, a crossover emerges.

These results help rule out a whole class of explanation for the poor performance of autistic children on false-belief tasks. For example, if autistic children perform poorly on false-belief tasks because of limited working memory, because of poor executive function, or because of impaired counterfactual reasoning, then why did the photographs/maps tasks not also demand these things? Similarly, for impaired event memory, for poor attention shifting, for poor mental imagery, and for other "general" impairments, it is hard to see why false-belief problems require the favored resource while other representation tasks do not. These findings challenge accounts that rely on an impairment in a general capacity.

The double dissociations in figure 85.4 suggest that although autistic children possess the general problem-solving resources required by the false-belief task, they are impaired in a specific representational competence,

FIGURE 85.3 The out-of-date photograph task. (Reproduced from Happé, 1995, by permission of the artist, Axel Scheffler.)

FIGURE 85.4 Autistic children show their age and ability advantage over normally developing 4-year-old children on tasks testing understanding of out-of-date public representations (top panel). When tasks with the same general structure but testing understanding of the mental state *belief* are introduced, autistic performance collapses, revealing a double dissociation between understanding public and mental representations (bottom two panels). (Data from Leslie and Thaiss, 1992.)

for example, the ToMM. The picture for normally developing children is crucially different and consistent with the idea that those who fail false-belief tasks do so because of limitations in general resources. Leslie and Thaiss proposed that the ToMM alone is not sufficient for the standard false-belief task, which requires a further mechanism. They called this extra mechanism selection processing (SP). They argued that the ToMM by

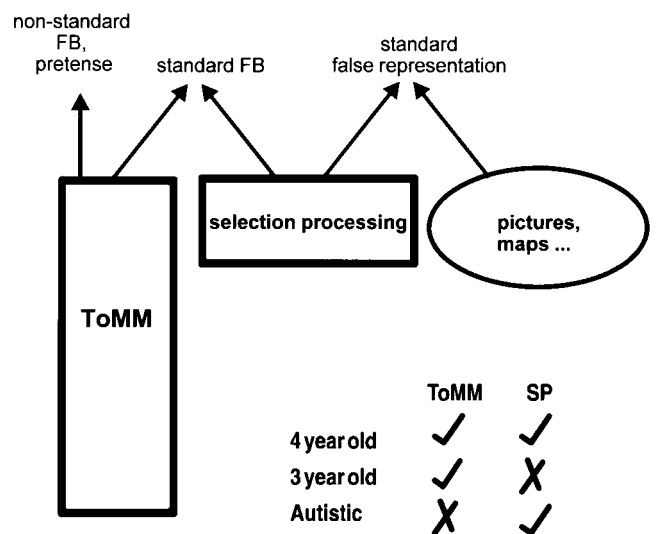

FIGURE 85.5 The theory of mind mechanism–selection processing (ToMM-SP) model of “theory of mind” development. Some problems require only the ToMM, for example, recognizing pretense and “modified” nonstandard false-belief tasks that typically are passed by normally developing 3-year-old children but are hard for autistic children. Standard false-belief tasks require the cooperation of SP with the ToMM, typically are failed by 3-year-olds and by autistic children, but typically are passed by 4-year-olds. Public representation tasks with the same task structure as standard false-belief tasks also require SP but do not involve the ToMM; these tasks are passed by normally developing 4-year-olds and autistic children. Normally developing children have an intact ToMM, but younger children have only weak SP. Autistic children are a mirror image of 3-year-olds with adequate SP but an impaired ToMM. (After Leslie and Thaiss, 1992.)

default attributes a belief with a content that reflects current reality. To succeed in a false-belief task, this default attribution must be *inhibited* and an alternative nonfactual content for the belief selected instead. Standard photograph tasks also demand SP. The normal 3-year-old fails both kinds of task because he or she has only weak SP. The successful 4-year-old has both an intact ToMM and sufficiently strong SP to pass standard tasks. The autistic child is a mirror image of the 3-year-old in so far as he or she has sufficiently strong SP (to pass photographs and maps) but an impaired ToMM. Figure 85.5 summarizes the ToMM-SP model of “theory of mind” development.

Examining failure on false belief: A second phase of research

Thus far, autistic children have been compared with normally developing 4-year-olds and nonautistic mentally retarded children who *pass* standard false-belief tasks. This work has established a specific impairment in “the-

ory of mind” abilities in autistic children. More recently, we have been studying the reason for autistic failure by comparing autistic children with normally developing 3-year-olds who also *fail* standard false-belief tasks. Do these two groups fail for the same reasons?

A number of studies are showing that these groups fail for different reasons. In the first such study, Roth and Leslie (1991) modified a false-belief task so that it became easier for 3-year-olds. Although most of the 3-year-olds in this task successfully attributed a false belief, most of the older autistic subjects did not. Roth and Leslie (1998) found differences between normally developing 3-year-olds and older autistic subjects on a “seeing leads to knowing” task. In a further experiment, Roth and Leslie (1998) showed that a modified false-belief task was easier than a standard false-belief task for 3-year-olds but not for autistic subjects, and that selection processing demands were a limiting factor on 3-year-old performance but not on autistic performance.

A number of modifications to the standard false-belief task are known to help 3-year-olds achieve better performance. The most minimal modification to the standard false-belief task that helps 3-year-olds is to ask, “Where will Sally look *first* for her marble?” Siegal and Beattie (1991) found that the addition of the single word “first” dramatically improved performance in a task in which children are told explicitly what Sally thinks. Surian and Leslie (1999) applied this minimal modification to a standard Sally and Ann task. One potential problem with asking where Sally will look first is that children simply might respond with where the object had been placed *first*. They then would appear to pass the task without ever considering Sally’s belief. Or children might assume, on being asked about a first look, that there will be a series of looks culminating in success and that the first look will therefore be a *failing* look. Again, responding with a failing look, children will appear to pass the task without ever considering Sally’s belief. To control for these possibilities, Surian and Leslie tested children on a control task in which Sally does not go away but instead watches while Ann moves the marble from the basket to the box. In this case, Sally knows where the marble is. If children in this condition follow either of the placed-first or failing-look strategies, they again will indicate the empty location; however, in the true-belief condition, such a response is wrong.

Normally developing children approximately 3 years and 9 months of age were tested in one of four conditions: a standard false-belief condition; an equivalent “standard” true-belief condition in which Sally stays and watches; a “look first” false-belief condition; and an equivalent “look first” true-belief condition. Only 30% of children in the standard false-belief condition passed,

Responses to “Look first” Question

FIGURE 85.6 Three-year-old children respond correctly to a “look first” prediction question in both false-belief and true-belief tasks, although correct responses are opposite in the two tasks. The “look first” modification therefore helps 3-year-old children to calculate belief. (After Surian and Leslie, 1999.)

a typical result, whereas all the children passed the corresponding true-belief version. In the “look first” conditions, 83% of the children passed false belief, whereas the same proportion passed the true-belief equivalent. The children in the latter two groups produced opposite responses when asked “Where will Sally look first for her marble?” depending on the belief status of Sally (figure 85.6).

The “look first” question helps younger children calculate a false belief. How does it do this? One possibility suggested by Siegal and Beattie (1991) is that it helps younger children recognize the questioner’s intention to ask about a belief rather than about reality. This may well be correct, but it does not indicate how it helps younger children do this, nor does it indicate why slightly older children do not need such help. Surian and Leslie (1999) suggest that by directing children’s attention to the first location of the object or to the possibility of failing looks, the question increases the salience of the first location *as the possible content* of Sally’s belief. This increased salience of the nonfactual content relative to the default reduces the need for inhibition, and thus, the task places less load on SP.

Surian and Leslie (1999) carried out a second experiment to determine whether the “look first” question also would help autistic children with false belief. In this study, a “think” question was asked before the usual control questions. After the control questions, the children were asked the “look first” version of the “prediction” question. With this design, the same child can be

Think versus Look First Questions

FIGURE 85.7 The “look first” question improves younger 3-year-old performance over a standard “think” false-belief question. No such improvement is seen in older autistic children. (After Surian and Leslie, 1999).

asked a standard task “think” question followed by a nonstandard “look first” question. A comparison group of normally developing children of approximately 3 years and 5 months of age also was tested in this way. The normally developing children again were helped by the “look first” question, although not as much as before, presumably because they were younger. The children with autism, by contrast, were not helped at all (figure 85.7).

In summary, normally developing 3-year-olds and older autistic children fail false-belief tasks for different reasons. There is growing evidence that normally developing children’s performance on false-belief problems is limited by processing resources rather than by an inability to represent belief states in others. These processing resources increase gradually over the preschool period and by the time the child is a little older than 4 years of age usually are sufficient to allow success on standard tasks. Older children with autism fail false-belief tasks for different reasons, apparently reflecting an impaired capacity to acquire normal “theory of mind” knowledge and skills. The emerging pattern supports the ToMM-SP model.

Inhibition in belief-desire reasoning

So far we have been considering why children fail false-belief tasks. It is equally important to develop models of how children pass these tasks. One requirement is the ability to represent the right kinds of information: information about agents, attitudes, anchors, and contents tied together in the relational structure modeled by the

M-representation. But simply being able to deploy concepts, like *pretend*, *desire*, and *believe*, does not guarantee that the child is able to solve particular “theory of mind” problems or already knows particular “theory of mind” facts.

We saw earlier that default belief attributions need to be inhibited to solve a false-belief problem and suggested that producing and controlling this inhibition may be a problem for young children. Performance changes due to the maturation of prefrontal cortex may be ubiquitous in development (Diamond, 1988; Goldman-Rakic, 1987), and Carlson and associates (1998) provide independent evidence of inhibitory involvement in the development of “theory of mind” skills.

It is useful to understand why belief attribution has a default bias. If *desires* set an agent’s goals, *beliefs* inform the agent about the state of the world. A belief that misinforms an agent is a useless, even dangerous, thing: beliefs *ought* to be true. Therefore, the best guess strategy for the naive belief attributer is to assume that an agent’s beliefs *are* true. Apparently, this is the strategy followed by the 3-year-old. However, false-belief tasks require that the default strategy be over-ridden. According to the ToMM-SP model, to do so requires inhibition of the prepotent attribution. The older child’s success shows that he manages this inhibition.

In a standard false-belief task, there are essentially two possible locations, the basket and the box, to which Sally’s belief about the marble might refer or which might be targets of Sally’s desire. The default belief attribution draws attention to one of these locations, namely, the current location of the object. To successfully solve the false-belief problem, the brain must disengage attention from this target and shift to the false-belief target. Inhibitory brain processes appear to be involved in other kinds of attention shifting, for example, in shifting covert visual attention (Posner and Presti, 1987; Rafal and Henik, 1994). According to the ToMM-SP model, belief-task target shifting also requires inhibitions.

Leslie and Polizzi (1998) tested the belief inhibition hypothesis by following up a finding of Cassidy (1995). Cassidy found that when the desire in a standard false-belief task is negative rather than positive, then 4-year-old children perform poorly. Typically, in false-belief task scenarios, Sally wants the target object; but in Cassidy’s task, Sally did *not* want to find the target. Leslie and Polizzi argued that the critical feature was not negation as such but whether the negation produced target shifting. Suppose a protagonist has a desire for whichever location does not have property X, and the only way to identify the NOT(X) location is to first identify the X location, and then choose the other one, that is, NOT(X). Identifying the protagonist’s desire target

this way involves the brain in target shifting. For example, Sally has a box and a basket that both contain some wool. She does not want to put a fish in the basket because there is a sick kitten nestling in the wool there (the kitten might get worse if it eats the fish). To identify where Sally wants to put the fish, one first identifies which location has the kitten, then, because this is *not* what Sally wants, one shifts from this location to the alternative. This creates a target-shifting desire.

Leslie and Polizzi (1998) pointed out an interesting feature of inhibition models of belief-desire reasoning. With true belief and positive desire, there is no target shifting. A false belief (with positive desire) involves a single target-shifting inhibition; so does a target-shifting desire (with true belief). However, when a false belief is combined with a target-shifting desire to produce a double inhibition task, the two inhibitions cannot simply sum their inhibitions because this will produce the wrong answer. Working through figure 85.8 will clarify this last point.

The four panels in figure 85.8 correspond to four kinds of behavior prediction task. The first is the simple true-belief plus positive-desire task: Sally wants the object and knows where it is. The pointing hand represents a mental index that the brain uses to indicate the target of Sally's belief and desire, and therefore the answer to the prediction task. In this model, belief and desire targets are identified in parallel. The next panel is the standard false-belief task. Here the first belief-desire index again indicates the location that contains the object because the initial belief attribution always is the default true belief, that is, where someone *should* think the object is. But in this task, the protagonist's belief is false and so, to succeed, the subject must inhibit this index. In the second panel, the inhibition is visualized by the "inhibition arm" reaching in to weaken the index. Because the initial target is inhibited, the index moves across to the alternate location, yielding the correct prediction that the protagonist will look in the empty location.

The third panel in figure 85.8 shows a true-belief with target-shifting desire. Again, the initial belief index shows the default true-belief location. The initial desire index shows the same target because the protagonist desires the NOT(X) location and the only way to identify that is to first identify the X location, then cancel it in favor of NOT(X). So in this panel, the inhibition arm inhibits the desire target and again the index moves to the empty location, generating the correct prediction.

The final panel shows how to predict behavior when the protagonist's belief is false and desire "negative." Once again, the belief-desire index initially is placed against the full location. But now two inhibitions must

Inhibitory processing in belief tasks

Inhibition of inhibition

FIGURE 85.8 A model of selection processing in belief-desire reasoning. The panels are arranged to illustrate a 2×2 factorial design with rows \pm desire and columns \pm belief. The pointing hand represents a mental index indicating the target of belief desire and thus, the answer to a "prediction of behavior" question. The grabbing arm represents an inhibitory brain process that weakens an index to which it is applied (reduced shading). Indexes are set initially for true belief and positive desire but subsequently inhibited if the belief is false (second panel) or the desire "negative" (third panel). Weakening of an index causes the index to move to the alternate location. The final panel shows double inhibitions canceling out, rather than summing. This gives the correct answer to false-belief with "negative-desire" problems. (After Leslie and Polizzi, 1998.)

be mobilized, one for the belief because it is false and one for the desire because it is a desire for NOT(X). If both these inhibitions are applied, as before, to the initial target, then it will be inhibited doubly and the index again will move to the empty location. But this time, predicting the empty location is wrong. If Sally wrongly believes the sick kitten to be in the left-hand location and does not want to put the fish in with the kitten, then Sally will try to put the fish in the right-hand location, where the kitten is. To get the correct answer, the two inhibitions cannot be applied in the usual way. Instead, one inhibition must inhibit the other so

that no inhibition reaches the initial target. The index then does not move, and Sally's behavior is predicted correctly. Even though logically, double inhibition problems have the same answer as simple true-belief + positive-desire tasks, the model predicts difficulty from marshaling an inhibition of inhibition.

Leslie and Polizzi (1998) tested the aforementioned prediction on a group of 4-year-olds who passed a standard false-belief task. One half of the children were given a true-belief with target-shifting desire task to measure how difficult it was for them to shift targets from a desire. Only a single child out of 16 tested failed the true-belief task, presumably because shifting from desire targets is easy for 4-year-olds who can target shift in a standard false-belief task. The other half of the subjects were tested with a false belief coupled with target-shifting desire. Here the results were dramatically different. Only 38% of this group correctly predicted which box Sally would approach with the fish.

To answer "think" questions requires calculating belief only; prediction of behavior requires taking into account both belief and desire. Despite this, children's success on "think" and "prediction" in standard tasks is tightly linked. So it is particularly interesting that all of the aforementioned children who failed "prediction" had, immediately before this, passed a "think" question.

The same pattern was found in a second experiment in which Leslie and Polizzi examined whether the aforementioned effects are caused by the linguistic demands of the negation used in stating the desire. Children were introduced to the "Mixed-up Man," a character who always does the opposite of what he wants: if he wants to pat a dog, he pats a cat; if he wants to eat ice cream, he eats a carrot. A scenario was constructed similar to the Sally-with-fish-and-kitten story but with the Mixed-up Man looking for a Mexican jumping bean which, unbeknownst to him, jumps from one box to the other. The key point is that the Mixed-up Man's desire was entirely positive but his behavior was opposite, so that negation did not appear in the protocol. Nevertheless, to predict his behavior, one first had to identify the target of a normal man's action, then shift to the alternate. From the point of view of selection-inhibition theory, what is critical is not negation but whether tasks are processed such that target shifting occurs. Indeed, the false beliefs in standard tasks always are positive but, according to the SP hypothesis, involve target shifting.

The novel Mixed-up Man introduced general difficulty because a substantial number of children failed the true-belief version of the task. Despite being far from ceiling on behavioral target shifting, significantly more

Prediction of behavior in belief tasks

FIGURE 85.9 Four-year-old children who have passed a standard false-belief task can easily combine a "negative" (target-shift) desire with a true belief, but combination with a false belief is very hard. A "target-shift behavior" task was fairly difficult for these children, even with true belief but overwhelmingly difficult when combined with false belief. In both cases, false-belief calculations were difficult even though the false belief was available in memory as shown by ceiling performance on a "think" question. (After Leslie and Polizzi,

children failed the double inhibition version. Results from both experiments are shown in figure 85.9.

One interpretation of these results is simply that 4-year-olds are so close to using up all their resources in solving a false-belief task that the addition of *any* further complexity pushes them below threshold. Even the tiny demand from desire-target shifting is sufficient to produce a catastrophic effect. However, this seems unlikely in view of the robustness of 4-year-old performance on a wide variety of standard false-belief tasks (Gopnik 1993), and the lack of reports of other minor modifications that seriously disrupt their performance. However, what is especially intriguing about our findings with double inhibition is that the false-belief calculation should contribute *any* difficulty at all to prediction. Recall that the child solved the false-belief problem to answer the "think" question. All the child has to do then is *remember the answer* for 3 seconds and combine it with *desire* to predict behavior. It is deeply puzzling on a resource model why this task should be any harder than the easy true-belief version: there too, the child simply has to remember the true belief attributed seconds earlier and combine it with desire to predict behavior. It is as if a child is asked to calculate $2 + 2$ (hard), manages to get the right answer, then is asked to add 1 to that, and, in response, proceeds to calculate, not $4 + 1$ (easy), but $2 + 2 + 1$ (extremely hard).

The inhibition of inhibition model explains the aforementioned effect only on the assumption that prediction mandates recalculation of belief despite the answer's availability in memory. Such rigid behavior might reflect the modular character of the ToMM. However, Leslie and Polizzi (1998) proposed a second inhibition model that accounts for these findings without assuming mandatory recalculation. The alternative model is based on the idea of *inhibition of return*. Inhibition of return is an effect familiar from studies of visual attention. It is harder to return attention to a visual target that has been previously attended then disengaged from than it is to attend to the target for the first time (Rafal and Henik, 1994). The model in figure 85.10 assumes that belief (and therefore the belief target) is calculated first and desire targets identified relative to belief. In the critical doubled case, the true-belief target is inhibited first, causing the index to shift to the other location. The desire target is set initially to this second location but, because the desire is "negative," this too must be inhibited, forcing return to the initial location. But the initial location still is inhibited, making return to it difficult. Now, because the first target was inhibited in the process of answering the "think" question correctly, even if the answer is remembered simply for a few seconds, the double inhibition prediction requires return to that still inhibited target. Even without mandatory recalculation, this will be difficult.

One recent study may indicate that recalculation is mandatory. Polizzi and Leslie (1999) tested a group of 4-year-old standard false-belief passers on the "double inhibition" task, outlined previously, but this time instead of asking where Sally would go with the fish, they asked where Sally would go *first*. Recall that asking a "look first" question helps 3-year-old children pass an otherwise standard false-belief task. Surian and Leslie (1999) hypothesized that this was because the word "first" made the nonfactual content more salient, reducing the need for inhibition of the default content. If "look first" works that way for 3-year-olds, might it also help 4-year-olds on double inhibition tasks? Polizzi and Leslie (1999) found that indeed it does: 81% of a group of 4-year-olds succeeded on the double inhibition task when asked the "look first" question. For 4-year-olds to be helped in this way, prediction must force recalculation of belief.

Summary

Rather than assume that because mental state concepts are abstract they can only be acquired by the child constructing a theory, I analyze "theory of mind" as a mechanism of selective attention. Mental state concepts

FIGURE 85.10 An alternative model of inhibitory processing in belief-desire reasoning. Instead of identifying the target of belief and desire in parallel, in this model belief targets are identified first and desire targets second. Desire targets are identified in relation to belief targets. Again, indexes are set initially for true belief and positive desire but, subsequently, the belief target is inhibited if the belief is false (second panel) and the desire target inhibited if the desire is "negative" (third panel). The final panel shows the resulting sequence in the double inhibition task. First, the target of true belief is identified and inhibited, causing the belief target to move to the alternative. The target of positive desire then is identified in relation to the new false belief target. Finally, the positive-desire target is inhibited, forcing return to the still inhibited true-belief target. (After Leslie and Polizzi, 1998).

simply allow the brain to attend selectively to corresponding mental state properties of agents and thus permit learning about those properties. Autistic children are impaired specifically in this attentional mechanism and find it hard to learn about the mental life of agents. Normally developing preschoolers acquire greater flexibility in attending to the contents of mental states, in particular, to the contents of beliefs that are false. The first information processing models of belief-desire reasoning were outlined.

1. Leekam and Perner (1991) found exactly equal numbers of passers and failers, whereas Slaughter (1998) and Perner and associates (in press) used nonparallel task structures, voiding the comparison.

86 The Cognitive Neuroscience of Autism: Evolutionary Approaches

SIMON BARON-COHEN

ABSTRACT An evolutionary approach to the cognitive neuroscience of autism generated the “theory of mind” (ToM) hypothesis. Most of its predictions of selective deficits in this domain have been confirmed. Currently attempts are being made to isolate the brain basis of the ToM deficits in autism. The ToM hypothesis has considerable explanatory power in relation to the “triad symptoms” of autism (social, communication, and imagination abnormalities) but has little relevance to the nontriad symptoms (attention to detail, islets of ability, and obsessions). An evolutionary hypothesis to account for these in terms of superior folk physics is discussed.

This chapter illustrates how an evolutionary approach has generated a key hypothesis in the cognitive neuroscience of autism. It then reintroduces the evolutionary approach to generate a new hypothesis for those features that are not yet well understood. But first, what is autism?

Autism is considered to be the most severe of the childhood neuropsychiatric conditions. It is diagnosed on the basis of abnormal development of social behavior, communication, and imagination, often in the presence of marked obsessional, repetitive, or ritualistic behavior (APA, 1994). In an attempt to understand the so-called “triad” impairments in autism (social, communication, and imagination abnormalities), my colleagues and I adopted an evolutionary framework. We asked the following questions: (1) Might mechanisms for understanding and interacting with the social world be specialized adaptations, universal both to current hominids and ancestrally? (2) If so, what might such ancient cognitive mechanisms be? (3) Could such mechanisms become selectively impaired as a result of a genetic factor? (4) Might autism be such a case of genetic caused impairment to specialized social-cognitive mechanisms?

To answer these questions we turned to the philosophical, primatological, and human developmental literatures as pointers to the prerequisites for hominid social interaction. Three key texts led to the same clear conclusions: Human social life is characterized by the neces-

sary adoption of the “intentional stance” (Dennett, 1987), that is, understanding action by ascribing mental states (beliefs, desires, intentions, etc.) to agents; humans appear to do this universally, whilst chimpanzees (or other nonhuman primates) only do this in a very limited way, if at all (Premack and Woodruff, 1978); and in the normal case even a 4-year-old child can pass a shockingly complex test of social intelligence or mental state ascription, namely, a test of understanding *false beliefs* (Wimmer and Perner, 1983). This fundamental and apparently uniquely human ability has been called a *theory of mind* (ToM). My colleagues and I therefore set out to test the ToM hypothesis of autism—that such children might for genetic reasons have a selective deficit in this most essential of neurocognitive mechanisms (Baron-Cohen, Leslie, and Frith, 1985). The relevant evidence is summarized next.

The theory of mind hypothesis: Experimental evidence

FIRST-ORDER THEORY OF MIND TESTS *First-order* tests involve inferring what one person thinks, knows, intends, or desires. There is a good deal of experimental evidence to review, so this section is necessarily concise. For clarity, different cognitive tests used are in italics.

Most children with autism are at chance on tests of the *mental-physical distinction* (Baron-Cohen, 1989a). They also have been shown to have an appropriate understanding of the functions of the brain but have a poor understanding of the *functions of the mind* (Baron-Cohen, 1989a). That is, they do not spontaneously mention the mind’s mental function (in thinking, dreaming, wishing, deceiving, etc.). They also fail to make the *appearance-reality distinction* (Baron-Cohen, 1989a). They fail a range of *first-order false belief* tasks, that is, they fail to distinguish between their own current belief and that of someone else (Baron-Cohen, Leslie, and Frith, 1985; Baron-Cohen, Leslie, and Frith, 1986; Leekam and Perner, 1991; Perner et al., 1989; Reed and Peterson, 1990; Swettenham et al., 1996). They also fail tests assessing whether they understand the principle that “*seeing leads*

SIMON BARON-COHEN Departments of Experimental Psychology and Psychiatry, University of Cambridge, Cambridge, U.K.

FIGURE 86.1 The “seeing leads to knowing” test.

to *knowing*” (Baron-Cohen and Goodhart, 1994; Leslie and Frith, 1988). For example, when presented with two dolls, one of which touches a box and the other of which *looks inside* the box, then asked “Which one *knows* what’s inside the box?” they are at chance in their response (figure 86.1). In contrast, normal children of 3 to 4 years of age correctly judge that it is the one who looked who knows what’s in the box.

Children with autism are at chance on a test of *recognizing mental state words* (like “think,” “know,” and “imagine”) in a wordlist (Baron-Cohen et al., 1994). They also do not produce the same range of mental state words in their spontaneous speech (Baron-Cohen, Leslie, and Frith, 1986; Tager-Flusberg, 1992). They also are impaired in the production of spontaneous *pretend play* (Baron-Cohen, 1987; Lewis and Boucher, 1988; Wing and Gould, 1979; Ungerer et al., 1981). Pretend play is relevant here because it is thought to involve understanding the mental state of pretending. Although they can understand simple causes of emotion (such as situations and desires), most children with autism have difficulty on tests of understanding more *complex causes of emotion* (such as beliefs) (Baron-Cohen, 1991a; Baron-Cohen, Spitz, and Cross, 1993).

They also fail tests of recognizing *the eye-region of the face* as indicating when a person is thinking and what a person might want (Baron-Cohen et al., 1995; Baron-Cohen and Cross, 1992). Children and adults without autism use gaze to infer both of these mental states. They fail a test of being able to *monitor their own intentions* (Phillips, Baron-Cohen, and Rutter, 1998). That is, they are poor at distinguishing whether they “meant” to do something or whether they did something accidentally.

They also have problems on tests of *deception* (Baron-Cohen, 1992; Sodian and Frith, 1992; Yirmiya,

Solomonica-Levi, and Shulman, 1996), a result that would be expected if one was unaware that people’s beliefs can differ and therefore can be manipulated. They also fail tests of *understanding metaphor, sarcasm, and irony*—these all being intentionally nonliteral statements (Happe, 1993). Indeed, they fail to produce most aspects of *pragmatics* in their speech (Baron-Cohen, 1988; Tager-Flusberg, 1993) and fail to recognize violations of pragmatic rules, such as the Gricean Maxims of conversational cooperation (Surian, Baron-Cohen, and Van der Lely, 1996). Because many pragmatic rules involve tailoring one’s speech to what the listener needs to know, or might be interested in, this can be seen as intrinsically linked to a theory of mind. Most children with autism also have difficulties in tests of *imagination* (Scott and Baron-Cohen, 1996), for example, producing drawings of impossible or totally fictional entities such as two-headed men. This could reflect a difficulty in thinking about their own mental state of imagination or reflect difficulties in flexible behavior (Leevers and Harris, 1998). Supporting an imagination deficit, they also do not show the normal facilitation effect of imagination on logical reasoning (Scott, Baron-Cohen, and Leslie, in press), unlike normally developing children. Performance on ToM tasks by children with autism has been found to correlate with real-life social skills, as measured by a modified version of the Vineland Adaptive Behaviour Scale (Frith, Happé, and Siddons, 1994).

SECOND-ORDER, ADOLESCENT, AND ADULT THEORY OF MIND TESTS A small minority of children or adults with autism pass first-order false belief tests. However, these individuals often fail *second-order false belief tests* (Baron-Cohen, 1989b), that is, tests of understanding what one character believes another character thinks. Such second-order reasoning usually is understood by normal children of 5 to 6 years of age (Sullivan, Zaitchik, and Tager-Flusberg, 1994), and yet individuals with autism with a mental age above this level may fail these tests. This suggests that there can be a *specific developmental delay* in theory of mind at a number of different points. Some individuals with autism who are very high functioning (in terms of intelligence quotient [IQ] and language level), and who are old enough, may pass even second-order tests (Bowler, 1992; Happe, 1993; Ozonoff, Pennington, and Rogers, 1991). Those who can pass second-order tests, however, may have difficulties in *understanding stories* in which characters are motivated by complex mental states such as bluff and double bluff (Happe, 1994). Equally, such able subjects have difficulties in decoding complex mental states from the expression in the eye-region of the face (Baron-Cohen, Jolliffe,

FIGURE 86.2 An item from the “reading the mind in the eyes” test. Is this face concerned or unconcerned?

Mortimore, and Robertson, 1997; Baron-Cohen, Wheelwright, and Jolliffe, 1997). Examples of the *Eyes Test* are shown in figure 86.2. Again, this suggests that the mind-reading deficit may only be detectable in such high-level, older subjects using sensitive, age-appropriate tests.

Similarly, children with Asperger’s syndrome (AS) may pass first- and second-order ToM tests but fail to detect *faux pas* in speech (Baron-Cohen et al., in press). Detecting *faux pas*, of course, is all about detecting who said the “wrong” thing—that is, detecting who said something that the listener should not *know* about. Finally, parents of children with AS, at least one of whom presumably carries the genes for AS, also show difficulties in attributing mental states when just the eye-region of the face is available (Baron-Cohen and Hammer, 1997).

For this reason, autism has been conceptualized as involving “mindblindness” to *varying degrees* (Baron-Cohen, 1990, 1995).

UNIVERSALITY To test whether the ToM deficit is universal in autism, more complex, subtle, or age-appropriate ToM tests may have to be used. When these have been used, ToM deficits do appear to be universal in autism and AS (Baron-Cohen, Jolliffe, et al., 1997). A different approach to addressing the universality question is to adopt Uta Frith’s suggestion (Frith, 1989) that there should be no cases of someone with an autism spectrum condition who passes a ToM test at the right chronological or mental age. (Thus, even a child with AS, if tested at 4 years old, should fail a false-belief test, even if he or she can pass it when retested at 6 years, for example. Such a pattern would fit the specific developmental delay hypothesis [Baron-Cohen, 1989b].)

VALIDITY Some authors (Waterhouse, Fein, and Modahl, 1996) have claimed that no correlation between ToM deficits and social skills is found. In fact, when the *relevant* social skills are assessed (namely, social skills in-

volving mentalizing) strong correlations are found (Frith, Happe, and Siddons, 1994). A further point surrounding validity is that because ToM skills only appear in the preschool years, and yet autism develops by the end of the first year of life, this may mean that ToM deficits cannot be a core of the condition (Rutter and Bailey, 1993). This argument is wrong simply because it ignores the work on infancy precursors to ToM, which is reviewed next.

INFANCY PRECURSORS TO THEORY OF MIND Leslie (1987) proposed that normally, a theory of mind already is evident in the capacity for pretense, and in children with autism, an early manifestation of the ToM deficit lies in their inability to pretend. Why? In his view, to understand that someone else might *pretend* that “this banana is real,” the child (according to Leslie) would need to be able to represent the agent’s *mental attitude* toward the proposition. One idea, then, is that ToM is first evident from approximately 18 to 24 months of age in the normal toddler’s emerging pretend play.

However, there is some evidence that ToM might have *even earlier* developmental origins. There are severe deficits in *joint attention* skills in children with autism (Sigman et al., 1986). Joint attention skills are those behaviors produced by the child that involve monitoring or directing the target of attention of another person, so as to coordinate the child’s own attention with that of somebody else (Bruner, 1983). Such behaviors include the pointing gesture, gaze-monitoring, and showing gestures, most of which are absent in most children with autism. Joint attention behaviors normally are fully developed by about 14 months of age (Butterworth, 1991; Scaife and Bruner, 1975), so their absence in autism signifies a very early-occurring deficit.

What is the evidence for lack of joint attention in autism? One study (Baron-Cohen, 1989d) found that young children (younger than 5 years old) with autism produced one form of the pointing gesture (imperative pointing, or pointing to request) while failing to produce another form of pointing (declarative pointing, or pointing to share interest). This dissociation was interpreted in terms of the declarative form of pointing alone being an indicator of the child monitoring another person’s mental state—in this case, the mental state of “interest,” or “attention.” More recent laboratory studies have confirmed the lack of spontaneous gaze-monitoring (Charman et al., 1997; Leekam et al., 1997; Phillips, Baron-Cohen, and Rutter, 1992; Phillips et al., 1996). Absence of joint attention at 18 months of age, in combination with an absence of pretend play, is a very strong predic-

tor of autism, both in a high-risk study of siblings who are undiagnosed (Baron-Cohen, Allen, and Gillberg, 1992) and in a random population study (Baron-Cohen et al., 1996). In the latter study, 16,000 children at 18 months of age were screened by their health visitors for these behaviors using the Checklist for Autism in Toddlers (CHAT). Just 12 children of the total population lacked joint attention and pretend play, 11 of whom were discovered to have an autism spectrum disorder.¹ The joint attention deficit in autism has received a great deal of research attention and currently is one of the best validated cognitive deficits in the condition (Mundy, 1995; Mundy and Crowson, 1997; Mundy, Sigman, and Kasari, 1990, 1994).

The finding of both joint attention and ToM deficits in autism may not be a coincidence if joint attention is a *precursor* to the development of a ToM. This is plausible because joint attention involves attending to another person's mental state of attention (Baron-Cohen, 1989c, 1989d, 1991b).

DOES THE THEORY OF MIND DEFICIT IMPLY MODULARITY? One possibility is that there may be a particular part of the brain that normally is responsible for understanding mental states that is specifically impaired in autism. This may be modular, as in Leslie's proposal of an innate theory of mind mechanism (Leslie, 1987, 1991; Leslie and Roth, 1993). Leslie (see also chapter 85) suggests that the function of such a mechanism is to represent information in a data-structure of the following form: [**Agent-Attitude-"Proposition"**]-for example: [Fred-thinks-"the safe is behind the Picasso"]. Such a proposal is sufficient to allow representation of the full range of mental states, in the attitude slot. Leslie's computational analysis has been widely accepted, although the innate modularity claim is more controversial (Caruthers, 1996; Russell, 1997b). Future work needs to focus on testing this claim against alternatives. For example, lower level social-perception mechanisms (an Eye-Direction Detector [EDD], an Intentionality Detector [ID], and a Shared Attention Mechanism [SAM]) may provide input to ToM, so that what is innate may be an attentional bias to relevant social information (faces, actions, eyes) (Baron-Cohen, 1994). Russell (1997a) argues that the ToM deficit can be produced by nonmodular, executive dysfunction.

Note that the modularity thesis of ToM has been tested in a series of single cases of neurological patients: (1) A patient with severe specific language impairment (SLI) but with intact ToM demonstrates the potential independence of language and ToM (Van der Lely, 1997). (2) A patient with impaired executive function (EF) but intact ToM demonstrates the potential independence of

EF and ToM. Some patients with Tourette's syndrome meet these criteria (Baron-Cohen, Robertson, and Moriarty, 1994). (3) A patient with intact EF but impaired ToM also suggests the independence of these two cognitive domains (Baron-Cohen, et al., in press). (4) A person with a very high IQ but ToM impairments demonstrates the existence of pure deficits in social intelligence, independent of general intelligence (Baron-Cohen et al., in press). (5) Patients with low IQs but intact ToM prove the same point. Patients with Williams syndrome fulfill this criterion (Tager-Flusberg, Boshart, and Baron-Cohen, 1998).²

It is entirely possible that the ToM deficit in autism occurs for genetic reasons because autism appears to be strongly heritable (Bailey et al., 1995; Bolton and Rutter, 1990; Le Couteur et al., 1996). The idea that the development of ToM normally is under genetic/biological control is consistent with evidence from cross-cultural studies. Normally developing children from markedly different cultures seem to pass tests of theory of mind at roughly the same ages (Avis and Harris, 1991). Which brain areas might be involved in ToM?

THE NEURAL BASIS OF THEORY OF MIND Exactly which part of the brain might subserve ToM is not yet clear, although candidate regions include the following: the right *orbitofrontal cortex*, which is active when subjects are thinking about mental state terms during functional imaging using single photon emission computed tomography (SPECT) (Baron-Cohen et al., 1994); and the *left medial frontal cortex*, which is active when subjects are drawing inferences about thoughts while undergoing positron-emission tomography (PET) scan (Fletcher et al., 1995; Goel et al., 1995). The first PET study to look at adults with autism/AS during a ToM task shows that such patients do not show the same patterns of neural activation when thinking about other minds (Happé et al., 1996); other candidate regions include the *amygdala* (Baron-Cohen and Ring, 1994). Ongoing studies suggest that adult patients with acquired amygdala lesions have difficulties with advanced (or adult-level) ToM tasks (Andy Young, personal communication, 1999), and a recent functional magnetic resonance imaging (fMRI) study of ToM using the Eyes Task (described earlier) found that although normal controls used areas of the frontotemporal cortex and the amygdala, high-functioning adults with autism or AS did not activate the amygdala during this task (Baron-Cohen et al., 1999). Finally, the demonstration of a joint attention deficit in autism and the role that the *superior temporal sulcus* in the monkey brain plays in the monitoring of gaze-direction (Perrett et al., 1985) has led to the idea that the superior temporal sulcus

may be involved in the development of a ToM (Baron-Cohen and Ring, 1994).

SUMMARY The ToM deficit in autism is present to varying degrees in individuals of different ages with autism or AS. It can be seen at least as early as 18 months of age, in the form of an absence of joint attention and pretend play; and this is not only of interest to basic science but is of clinical significance in improving early diagnosis. Future research needs to explore the first year of life, using prospective studies of high-risk populations, to better understand the ontogenesis of both ToM and autism. The ToM hypothesis is successful in explaining the “triad” symptoms of autism (social, communication, and imagination deficits) but has almost no relevance to the “nontriad” symptoms (attention to detail, strong obsessions, islets of ability). What might explain these?

Reintroducing the evolutionary framework to explain the nontriad symptoms of autism

Existing attempts to account for the nontriad symptoms of autism essentially paint these symptoms in terms of deficits (central coherence is said to be “weak” [Frith, 1989], or executive control is said to be “dysfunctional” [Russell, 1997a]). In this section, I rethink the nontriad features to keep evolutionary considerations central and to emphasize these features as reflecting superior abilities, not deficits.

The evolutionary view of cognition is in terms of domain specificity. A number of theorists have suggested that rather than adopting the traditional ways of carving-up of cognition, one should instead study cognitive development in terms of a small set of “core domains of cognition,” motivated by an evolutionary framework (Carey, 1985; Gelman and Hirschfield, 1994; Pinker, 1997; Sperber et al., 1995; Wellman and Gelman, 1998). This refers to domains of knowledge that develop very early in human infancy, with a universal pattern of ontogenesis, and an initial state that is likely to be in part innate. The universalist approach here immediately underlines that these aspects of cognition may be fundamental and result from evolutionary selection pressures at least as old as early hominids, if not older.

A consensus among these researchers is that two such core domains of cognition are *folk psychology* and *folk physics*. The term “folk” is intended to emphasize that this knowledge develops without any formal teaching. Some authors also use the terms “intuitive psychology” and “intuitive physics.” Folk psychology is our everyday ability to understand and predict an agent’s behavior in

terms of intentional states such as goals, beliefs, and desires. It is what we considered earlier, under the heading of theory of mind. Folk physics is our everyday ability to understand and predict the behavior of inanimate objects in terms of principles relating to physical causality.

As indicated in the section on the experimental evidence of the ToM hypothesis, an impaired folk psychology characterizing autism seems beyond any doubt. But it is plausible that there might also be an intact or even *superior* folk physics in autism. In the following discussion of this, we include the following within folk physics: understanding of objects, machines, physical-causality, and physical systems. How well are predictions from this view of autism confirmed?

There is a range of relevant evidence to consider. First, children with autism certainly understand physical causality (Baron-Cohen et al., 1986). They also seem to understand machines such as cameras (Leekam and Perner, 1991; Leslie and Thaiss, 1992), possibly better than mental age-matched controls. In addition, many of their obsessional interests center on machines and physical systems (Baron-Cohen, 1997; Baron-Cohen and Wheelwright, in press).

If *impaired folk psychology together with superior folk physics* were a good characterization of the cognitive phenotype of autism, then this also might constitute the “broader phenotype” of those first-degree relatives of children with autism who carry the relevant genes but express them to a lesser degree. Recent studies bear this out. First, parents of children with AS show impairments on an adult test of folk psychology (the Reading the Mind in the Eyes Test), together with a superiority on the Embedded Figures Test (Baron-Cohen and Hammer, 1997a). Exactly what the Embedded Figures Test is a test of is unclear, although at one level it measures how one analyzes wholes into their parts, and this may be a prerequisite of folk physics. Second, fathers of children with autism, as well as grandfathers, are over-represented in occupations such as engineering relative to occupations such as social work (Baron-Cohen, Wheelwright, et al., 1997). Engineering is a clear example of an occupation that requires good folk physics, whereas social work is a clear example of an occupation that requires good folk psychology. Similarly, students in the fields of math/physics/engineering are more likely to have a relative with autism than are students in the humanities (Baron-Cohen et al., 1998). These family studies all are consistent with the idea that the autistic spectrum phenotype at the cognitive level involves this *combination* of superior folk physics with impaired folk psychology. This is summarized in the model in figure 86.3 relating cognition to symptoms.

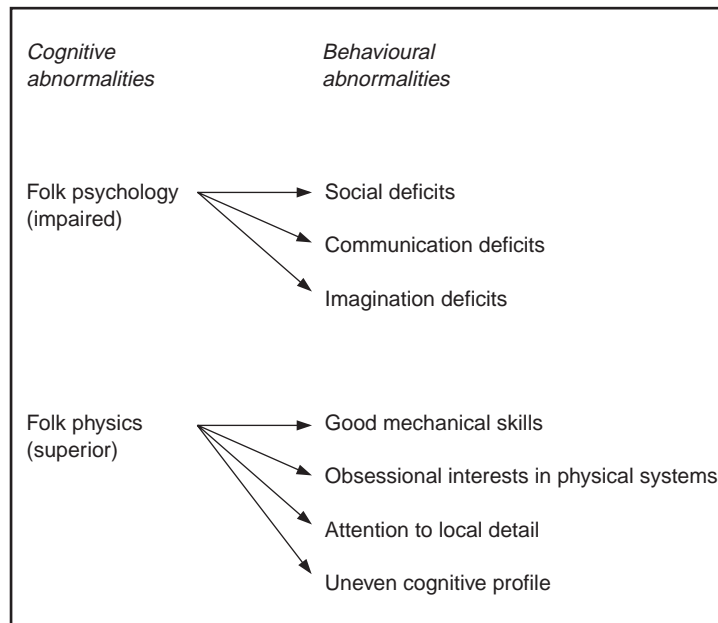

FIGURE 86.3 A model of the relationship between folk psychology and folk physics.

The extreme male brain theory of autism: A third evolutionary hypothesis

There is one more interesting evolutionary hypothesis to consider, and this picks up an old but undeveloped idea from Asperger (1944), who wrote “The autistic personality is an extreme variant of male intelligence. . . . In the autistic individual the male pattern is exaggerated to the extreme” (Frith, 1991). The extreme male brain (EMB) theory is explored in detail elsewhere (Baron-Cohen and Hammer, 1997b). One clue to the EMB theory is that in autism, the sex ratio is 4 males to 1 female (Rutter, 1978). The 4:1 sex ratio is true of autism when one includes individuals with this condition at all points on the IQ scale. If one restricts it to individuals with autism with an IQ in the normal range (referred to as either “high-functioning autism” or AS³), the sex ratio is even more dramatically biased against males: Wing (1988) estimates it as 9:1 (male:female), and Ehlers and associates (1997) recently documented a ratio of 40:0 (m:f). Because high-functioning autism or AS may be considered to be “pure autism” (i.e., not confounded by the effects of mental retardation; Frith, 1989), it may be that these sex ratios are more accurate estimates of how the sexes are affected differentially by this condition.

A second clue to the EMB theory is that superior folk physics skills (seen in autism and AS) also generally are associated with being male: the sex ratio in fields like engineering, math, and physics remains

heavily biased toward males. Whether this reflects biological or social factors has not been established. A third clue is that three recent studies have found sex differences in the rate of development of folk psychology/ToM skills (Baron-Cohen, Jolliffe, et al., 1997; Baron-Cohen et al., in press; Happe, 1995) in all cases showing a female superiority. The implication is that if the male brain⁴ involves this combination of impaired folk psychology and superior folk physics to a mild degree, in autism spectrum disorders this combination occurs to a more marked extent.

Conclusions

The evolutionary framework used might help explain why a condition like autism persists in the gene pool: The very same genes that lead an individual to have a child with autism can lead to superior functioning in the domain of folk physics. Pinker (1997) argues that the evolution of the human mind should be considered in terms of its evolved adaptedness to the environment. In his view, the brain needed to be able to maximize the survival of its host body in response to at least two broad challenges: the physical environment and the social environment. The specialized cognitive domains of folk physics and folk psychology can be seen as adaptations to each of these. One possibility is that a cognitive profile of superior folk physics along with impaired folk psychology could arise for genetic reasons because some brains are better adapted to understanding the social en-

vironment whereas other brains are better adapted to understanding the physical environment. Exactly why this relationship should occur between these two domains is not clear: Is this neural compensation by one domain over another? Are these two independent domains that can dissociate from one another to a greater or lesser extent? How are such domains constructed in the first place? These are questions for the future.

ACKNOWLEDGMENTS The author was supported by the Medical Research Council, the Wellcome Trust, and the Gatsby Foundation during the period of this work.

NOTES

1. In the paper reporting this result, the rate was 10 of 12 affected children. Subsequent follow-up of these cases reveals the rate is now 11 of 12.
2. Caution is needed to distinguish the innate modularity thesis of ToM from an acquired modularity thesis of ToM.
3. High-functioning autism is the term used when an individual of normal IQ meets criteria for autism, including a delay in the onset of speech; Asperger syndrome (AS) is the term used when an individual of normal IQ meets criteria for autism, but with no delay in the onset of speech (ICD-10, 1994).
4. Note that the theory therefore defines what constitutes the male brain. This cognitive profile does not have to be true of every biological male, of course. There are many individuals who are biologically male who do not have the male brain, as so defined. Equally, there are some individuals who are biologically female who have the male brain, so defined.

87 The Cognitive Neuroscience of Social Reasoning

LEDA COSMIDES AND JOHN TOOBY

ABSTRACT Cognitive scientists need theoretical guidance that is grounded in something beyond intuition. They need evolutionary biology's "adaptationist program": a research strategy in which theories of adaptive function are key inferential tools, used to identify and investigate the design of evolved systems. Using research on how humans reason about social exchange, the authors will (1) illustrate how theories of adaptive function can generate detailed and highly testable hypotheses about the design of computational machines in the human mind, and (2) review research that tests for the presence of these machines. This research suggests that the human computational architecture contains an expert system designed for reasoning about cooperation for mutual benefit, with a subroutine specialized for cheater detection.

Natural competences

Scientists have been dissecting the neural architecture of the human mind for several centuries. Dissecting its computational architecture has proven more difficult, however. Our natural competences—our abilities to see, to speak, to find someone beautiful, to reciprocate a favor, to fear disease, to fall in love, to initiate an attack, to experience moral outrage, to navigate a landscape, and myriad others—are possible only because there is a vast and heterogeneous array of complex computational machinery supporting and regulating these activities. But this machinery works so well that we do not even realize that it exists. Our intuitions blur our scientific vision. As a result, we have neglected to study some of the most interesting machinery in the human mind.

Theories of adaptive function are powerful lenses that allow one to see beyond one's intuitions. Aside from those properties acquired by chance or imposed by engineering constraint, the mind consists of a set of information-processing circuits that were designed by natural selection to solve adaptive problems that our ancestors faced, generation after generation. If we

know what these problems were, we can seek mechanisms that are well engineered for solving them.

The exploration and definition of adaptive problems is a major activity in evolutionary biology. By combining results derived from mathematical modeling, comparative studies, behavioral ecology, paleoanthropology, and other fields, evolutionary biologists try to identify (1) what problems the mind was designed to solve, (2) why it was designed to solve *those* problems rather than other ones, and (3) what information was available in ancestral environments that a problem-solving mechanism could have used. These are the components of what Marr (1982) called a "computational theory" of an information-processing problem: a task analysis defining what a computational device does and why it does it.

Because there are multiple ways of achieving any solution, experiments are always needed to determine which algorithms and representations actually evolved to solve a particular problem. But the more precisely you can define the goal of processing—the more tightly you can constrain what would count as a solution—the more clearly you can see what a program capable of producing that solution would have to look like. The more constraints you can discover, the more the field of possible solutions is narrowed, and the more you can concentrate your experimental efforts on discriminating between viable hypotheses.

In this way, theories of adaptive problems can guide the search for the cognitive programs that solve them. Knowing what cognitive programs exist can, in turn, guide the search for their neural basis. To illustrate this approach, we will show how it guided a research program of our own on how people reason about social interactions.

Some of the most important adaptive problems our ancestors had to solve involved navigating the social world, and some of the best work in evolutionary biology is devoted to analyzing constraints on the evolution of mechanisms that solve these problems. Constructing computational theories from these constraints led us to suspect that the human cognitive architecture contains expert systems specialized for reasoning about the social

LEDA COSMIDES Center for Evolutionary Psychology and Department of Psychology, University of California, Santa Barbara, Calif.

JOHN TOOBY Center for Evolutionary Psychology and Department of Anthropology, University of California, Santa Barbara, Calif.

world. If these exist, then their inference procedures, representational primitives, and default assumptions should reflect the structure of adaptive problems that arose when our hominid ancestors interacted with one another. Our first task analysis was of the adaptive information-processing problems entailed by the human ability to engage in social exchange.

Social exchange and conditional reasoning

In categorizing social interactions, there are two basic consequences that humans can have on each other: helping or hurting, bestowing benefits or inflicting costs. Some social behavior is unconditional: One nurses an infant without asking it for a favor in return, for example. But most social acts are delivered conditionally. This creates a selection pressure for cognitive designs that can detect and understand social conditionals reliably, precisely, and economically (Cosmides, 1985, 1989; Cosmides and Tooby, 1989, 1992). Two major categories of social conditionals are social exchange and threat-conditional helping and conditional hurting—carried out by individuals or groups on individuals or groups. We initially focused on social exchange (for review, see Cosmides and Tooby, 1992). A social exchange involves a conditional of the approximate form: *If person A provides the requested benefit to or meets the requirement of person or group B, then B will provide the rationed benefit to A.* (Herein, a rule expressing this kind of agreement to cooperate will be referred to as a *social contract*.)

We elected to study reasoning about social exchange for several reasons:

1. Many aspects of the evolutionary theory of social exchange (sometimes called *cooperation*, *reciprocal altruism*, or *reciprocation*) are relatively well developed and unambiguous. Consequently, certain features of the functional logic of social exchange could be confidently relied on in constructing *a priori* hypotheses about the structure of the information-processing procedures that this activity requires.

2. Complex adaptations are constructed in response to evolutionarily long-enduring problems. Situations involving social exchange have constituted a long-enduring selection pressure on the hominid line: Evidence from primatology and paleoanthropology suggests that our ancestors have engaged in social exchange for at least several million years.

3. Social exchange appears to be an ancient, pervasive, and central part of human social life. The universality of a behavioral phenotype is not a *sufficient* condition for claiming that it was produced by a cognitive adaptation, but it is suggestive. As a behavioral phenotype, so-

cial exchange is as ubiquitous as the human heartbeat. The heartbeat is universal because the organ that generates it is everywhere the same. This is a parsimonious explanation for the universality of social exchange as well: the cognitive phenotype of the organ that generates it is everywhere the same. Like the heart, its development does not seem to require environmental conditions (social or otherwise) that are idiosyncratic or culturally contingent.

4. Social exchange is relatively rare across species, however. Many species have the ability to recognize patterns (as connectionist systems do) or change their behavior in response to rewards and punishments (see chapter 81 of this volume). Yet these abilities alone are insufficient for social exchange to emerge, despite the rewards it can produce. This suggests that social exchange behavior is generated by cognitive machinery specialized for that task.¹

5. Finding procedures specialized for reasoning about social exchange would challenge a central assumption of the behavioral sciences: that the evolved architecture of the mind consists solely or predominantly of a small number of content-free, general-purpose mechanisms (Tooby and Cosmides, 1992).

Reasoning is among the most poorly understood areas in the cognitive sciences. Its study has been dominated by a pre-Darwinian view, championed by the British Empiricists and imported into the modern behavioral sciences in the form of the Standard Social Science Model (SSSM). According to this view, reasoning is accomplished by circuits designed to operate uniformly over every class of content (see chapter 81), and the mind has no content that was not derived from the perceptual data these circuits take as input. These circuits were thought to be few in number, content free, and general purpose, part of a hypothetical faculty that generates solutions to all problems: “general intelligence.” Experiments were designed to reveal what computational procedures these circuits embodied; prime candidates were all-purpose heuristics and “rational” algorithms—ones that implement formal methods for inductive and deductive reasoning, such as Bayes’s rule or the propositional calculus. These algorithms are jacks of all trades: Because they are content free, they can operate on information from any domain (their strength). They are also masters of none: To be content independent means that they lack any domain-specialized information that would lead to correct inferences in one domain but would not apply to others (their weakness).

This view of reasoning as a unitary faculty composed of content-free procedures is intuitively compelling to many people. But the discipline of asking what adaptive

information-processing problems our minds evolved to solve changes one's scientific intuitions/sensibilities. One begins to appreciate (1) the complexity of most adaptive information-processing problems; (2) that the evolved solution to these problems is usually machinery that is well engineered for the task; (3) that this machinery is usually specialized to fit the particular nature of the problem; and (4) that its evolved design must embody "knowledge" about problem-relevant aspects of the world.

The human computational architecture can be thought of as a collection of evolved problem-solvers. Some of these may indeed embody content-free formalisms from mathematics or logic, which can act on any domain and acquire all their specific content from perceptual data alone (Gigerenzer, 1991; Brase, Cosmides, and Tooby, 1998). But many evolved problem-solvers are expert systems, equipped with "crib sheets": inference procedures and assumptions that embody knowledge specific to a given problem domain. These generate correct (or, at least, adaptive) inferences that would not be warranted on the basis of perceptual data alone. For example, there currently is at least some evidence for the existence of inference systems that are specialized for reasoning about objects (Baillergeon, 1986; Spelke, 1990), physical causality (Brown, 1990; Leslie, 1994), number (Gallistel and Gelman, 1992; Wynn, 1992, 1995), the biological world (Atran, 1990; Hatano and Inagaki, 1994; Keil, 1994; Springer, 1992), the beliefs and motivations of other individuals (Baron-Cohen, 1995; Leslie, 1987; see also chapters 85 and 86), and social interactions (Cosmides and Tooby, 1992; Fiske, 1991). These domain-specific inference systems have a distinct advantage over domain-independent ones, akin to the difference between experts and novices: Experts can solve problems faster and more efficiently than novices because they already know a lot about the problem domain.

So what design features might one expect an expert system that is well engineered for reasoning about social exchange to have?

Design features predicted by the computational theory

The evolutionary analysis of social exchange parallels the economist's concept of trade. Sometimes known as "reciprocal altruism," social exchange is an "I'll scratch your back if you scratch mine" principle. Economists and evolutionary biologists had already explored constraints on the emergence or evolution of social exchange using game theory, modeling it as a repeated Prisoners' Dilemma. Based on these analyses, and on data from paleoanthropology and primatology, we developed a

computational theory (*sensu* Marr, 1982) specifying design features that algorithms capable of satisfying these constraints would have to have. For example:

1. To discriminate social contracts from threats and other kinds of conditionals, the algorithms involved would have to be sensitive to the presence of benefits and costs, and be able to recognize a well-formed social contract (for a grammar of social exchange, see Cosmides and Tooby, 1989). Social exchange is cooperation for *mutual benefit*. The presence of a benefit is crucial for a situation to be recognized as involving social exchange. The presence of a cost is not a necessary condition: providing a benefit may cause one to incur a cost, but it need not. There must, however, be algorithms that can assess relative benefits and costs, to provide input to decision rules that cause one to accept a social contract only when the benefits outweigh the costs.

2. The game theoretic analyses indicated that social exchange cannot evolve in a species or be sustained stably in a social group unless the cognitive machinery of the participants allows a potential cooperator to detect individuals who cheat, so that they can be excluded from future interactions in which they would exploit co-operators (Axelrod, 1984; Axelrod and Hamilton, 1981; Boyd, 1988; Trivers, 1971; Williams, 1966). In this context, a *cheater* is an individual who accepts a benefit without satisfying the requirements that provision of that benefit was made contingent upon. This definition does not map onto content-free definitions of violation found in the propositional calculus and in most other reasoning theories (e.g., Rips, 1994; Johnson-Laird and Byrne, 1991). A system capable of detecting cheaters would need to define the concept using contentful representational primitives, referring to illicitly taken *benefits*. The definition also is perspective dependent, because the item or action that one party views as a benefit, the other views as a requirement. Given "If you give me your watch, I'll give you \$10," you would have cheated me if you took my \$10 but did not give me your watch; I would have cheated you if I had taken your watch without giving you the \$10. This means that the system needs to be able to compute a cost-benefit representation from the perspective of each participant, and define cheating with respect to that perspective-relative representation.

In short, what counts as cheating is so content dependent that a detection mechanism equipped with a domain-general definition of violation would not be able to solve the problem of cheater detection. Hence, an expert system designed for conditional reasoning about social exchange should have a subroutine *specialized* for detecting cheaters.

TABLE 87.1
Computational machinery that governs reasoning about social contracts

Design features predicted (and established)
<ol style="list-style-type: none"> 1. It includes inference procedures specialized for detecting cheaters. 2. The cheater detection procedures cannot detect violations that do not correspond to cheating (e.g., mistakes when no one profits from the violation). 3. The machinery operates even in situations that are unfamiliar and culturally alien. 4. The definition of cheating varies lawfully as a function of one's perspective. 5. The machinery is just as good at computing the cost-benefit representation of a social contract from the perspective of one party as from the perspective of another. 6. It cannot detect cheaters unless the rule has been assigned the cost-benefit representation of a social contract. 7. It translates the surface content of situations involving the contingent provision of benefits into representational primitives, such as "benefit," "cost," "obligation," "entitlement," "intentional," and "agent." 8. It imports these conceptual primitives, even when they are absent from the surface content. 9. It derives the implications specified by the computational theory, even when these are not valid inferences of the propositional calculus (e.g., "If you take the benefit, then you are obligated to pay the cost" implies "If you paid the cost, then you are entitled to take the benefit"). 10. It does not include procedures specialized for detecting altruists (individuals who have paid costs but refused to accept the benefits to which they are therefore entitled). 11. It cannot solve problems drawn from other domains (e.g., it will not allow one to detect bluffs and double-crosses in situations of threat). 12. It appears to be neurologically isolable from more general reasoning abilities (e.g., it is unimpaired in schizophrenic patients who show other reasoning deficits; Maljkovic, 1987). 13. It appears to operate across a wide variety of cultures (including an indigenous population of hunter-horticulturists in the Ecuadorian Amazon; Sugiyama, Tooby, and Cosmides, 1995).
Alternative (by-product) hypotheses eliminated
<ol style="list-style-type: none"> 1. That familiarity can explain the social contract effect. 2. That social contract content merely activates the rules of inference of the propositional calculus. 3. That social contract content merely promotes (for whatever reason) "clear thinking." 4. That permission schema theory can explain the social contract effect. 5. That any problem involving payoffs will elicit the detection of violations. 6. That a content-independent deontic logic can explain the effect.

Based on evidence reviewed in Cosmides and Tooby, 1992.

3. Algorithms regulating social exchange should be able to operate even over unfamiliar contents and situations. Unlike other primates, who exchange only a limited array of favors (e.g., grooming, food, protection), humans trade an almost unlimited variety of goods and services. Moreover, one needs to be able to interpret each new situation that arises—not merely ones that have occurred in the past. Thus, the algorithms should be able to operate properly even in unfamiliar situations, as long as they can be interpreted as involving the conditional provision of benefits. This means the representational format of the algorithms cannot be tied to specific items with a fixed exchange rate (e.g., one could imagine the reciprocation algorithms of vampire bats, who share regurgitated blood, to specify an exchange rate in blood volume). From the surface content of a situation, the algorithms should compute an abstract level of representation, with representational primitives such as *benefit_{agent 1}*, *requirement_{agent 1}*, *agent 1*, *agent 2*, *cost_{agent 2}*, and so forth.

4. In the context of social exchange, modals such as "must" and "may" should be interpreted deontically, as referring to obligation and entitlement (rather than to necessity and possibility). As a result, cheating is taking a benefit one is not entitled to. It does not matter where terms such as "benefit taken" or "requirement not met" fall in the logical structure of a rule. In addition, there are constraints on when one should punish cheating, and by how much (Cosmides, 1985; Cosmides and Tooby, 1989).

Such analyses provided a principled basis for generating detailed hypotheses about reasoning procedures that, because of their domain-specialized structure, would be well designed for detecting social conditionals involving exchange, interpreting their meaning, and successfully solving the inference problems they pose (table 87.1). These hypotheses were tested using standard methods from cognitive psychology, as described below.

Part of your new job for the City of Cambridge is to study the demographics of transportation. You read a previously done report on the habits of Cambridge residents that says: **"If a person goes into Boston, then that person takes the subway."**

The cards below have information about four Cambridge residents. Each card represents one person. One side of a card tells where a person went, and the other side of the card tells how that person got there. Indicate only those card(s) you definitely need to turn over **to see if any of these people violate this rule.**

FIGURE 87.1 The Wason selection task (descriptive rule, familiar content). In a Wason selection task, there is always a rule of the form *If P then Q*, and four cards showing the values *P*, *not-P*, *Q*, and *not-Q* (respectively) on the side that the subject can see. From a logical point of view, only the combination of

P and *not-Q* can violate this rule, so the correct answer is to check the *P* card (to see whether it has a *not-Q* on the back), the *not-Q* card (to see whether it has a *P* on the back), and no others. Few subjects answer correctly, however, when given problems with descriptive rules, such as the problem in figure 87.1.

Computational theories (or task analyses) are important because they specify a mechanism's adaptive function: the problem it was designed by natural selection to solve. They are central to any evolutionary investigation of the mind, for a simple reason. To show that an aspect of the phenotype is an adaptation, one needs to demonstrate a fit between form and function: One needs *design evidence*. There are now a number of experiments on human reasoning comparing performance on tasks in which a conditional rule either did or did not express a social contract. These experiments—some of which are described below—have provided evidence for a series of domain-specific effects predicted by our analysis of the adaptive problems that arise in social exchange. Social contracts activate content-*dependent* rules of inference that appear to be complexly specialized for processing information about this domain. These rules include sub-routines that are specialized for solving a particular problem within that domain: cheater detection. The programs involved do not operate so as to detect potential altruists (individuals who pay costs but do not take benefits), nor are they activated in social contract situations in which errors would correspond to innocent mistakes rather than intentional cheating. Nor are they designed to solve problems drawn from domains other than social exchange; for example, they do not allow one to detect bluffs and double-crosses in situations of threat, nor do they allow one to detect when a safety rule has been violated. The pattern of results elicited by social exchange content is so distinctive that we believe reasoning in this domain is governed by computational units that are domain specific and functionally distinct: what we have called *social contract algorithms* (Cosmides, 1985, 1989; Cosmides and Tooby, 1992).

To help readers track which hypotheses are tested by each experiment, we will refer to the list in table 87.1. For example, D1 = design feature #1 (inference procedures specialized for detecting cheaters); B1 = byproduct hypothesis #1 (that familiarity can explain the social contract effect).

Tests with the Wason selection task

To test for the presence of the design features predicted, we used an experimental paradigm called the Wason selection task (Wason, 1966; Wason and Johnson-Laird, 1972). For more than 30 years, psychologists have been using this paradigm (which was originally developed as a test of logical reasoning) to probe the structure of human reasoning mechanisms. In this task, the subject is asked to look for violations of a conditional rule of the form *If P then Q*. Consider the Wason selection task presented in figure 87.1.

From a logical point of view, the rule has been violated whenever someone goes to Boston without taking the subway. Hence, the logically correct answer is to turn over the *Boston* card (to see if this person took the subway) and the *cab* card (to see if the person taking the cab went to Boston). More generally, for a rule of the form *If P then Q*, one should turn over the cards that represent the values *P* (a true antecedent) and *not-Q* (a false consequent).

If the human mind develops reasoning procedures specialized for detecting logical violations of conditional rules, this would be intuitively obvious. But it is not. In general, fewer than 25% of subjects spontaneously make this response. Moreover, even formal training in logical reasoning does little to boost performance on descriptive

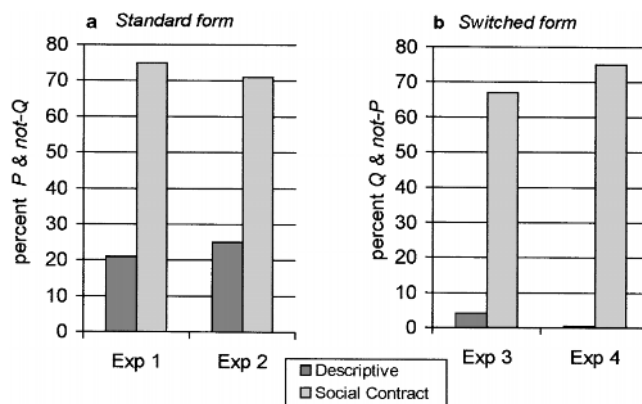

rules of this kind (Cheng et al., 1986; Wason and Johnson-Laird, 1972). Indeed, a large literature exists that shows that people are not very good at detecting logical violations of if-then rules in Wason selection tasks, *even when these rules deal with familiar content drawn from everyday life* (Manktelow and Evans, 1979; Wason, 1983).

The Wason selection task provided an ideal tool for testing hypotheses about reasoning specializations designed to operate on social conditionals, such as social exchanges, threats, permissions, obligations, and so on, because (1) it tests reasoning about conditional rules, (2) the task structure remains constant while the content of the rule is changed, (3) content effects are easily elicited, and (4) there was already a body of existing experimental results against which performance on new content domains could be compared.

For example, to show that people who ordinarily cannot detect violations of conditional rules can do so when that violation represents cheating on a social contract would constitute initial support for the view that people have cognitive adaptations specialized for detecting cheaters in situations of social exchange. To find that violations of conditional rules are spontaneously detected when they represent bluffing on a threat would, for similar reasons, support the view that people have reasoning procedures specialized for analyzing threats. Our general research plan has been to use subjects' inability to spontaneously detect violations of conditionals expressing a wide variety of contents as a comparative baseline against which to detect the presence of performance-boosting reasoning specializations. By seeing which content-manipulations switch on or off high performance, the boundaries of the domains within which reasoning specializations successfully operate can be mapped.

The results of these investigations were striking. People who ordinarily cannot detect violations of if-then rules can do so easily and accurately when that violation represents cheating in a situation of social exchange (Cosmides, 1985, 1989; Cosmides and Tooby, 1989, 1992). Given a rule of the general form, "If you take benefit B, then you must satisfy requirement R," subjects choose the *benefit accepted* card and the *requirement not met* card—the cards that represent potential cheaters. The adaptively correct answer is immediately obvious to almost all subjects, who commonly experience a "pop out" effect. No formal training is needed. Whenever the content of a problem asks one to look for cheaters in a social exchange, subjects experience the problem as simple to solve, and their performance jumps dramatically. In general, 65% to 80% of subjects get it right, the highest performance found for a task of this kind (supports D1).

This is true for familiar social contracts, such as, "If a person drinks beer, then that person must be over 19

Exp 1 & 3: Social contract = social rule
Exp 2 & 4: Social contract = personal exchange

FIGURE 87.2 Detecting violations of unfamiliar conditional rules: social contracts versus descriptive rules. In these experiments, the same, unfamiliar rule was embedded either in a story that caused it to be interpreted as a social contract or in a story that caused it to be interpreted as a rule describing some state of the world. For social contracts, the correct answer is always to pick the *benefit accepted* card and the *requirement not met* card. (A) For standard social contracts, these correspond to the logical categories *P* and *not-Q*. *P* and *not-Q* also happens to be the logically correct answer. More than 70% of subjects chose these cards for the social contracts, but fewer than 25% chose them for the matching descriptive rules. (B) For switched social contracts, the *benefit accepted* and *requirement not met* cards correspond to the logical categories *Q* and *not-P*. This is not a logically correct response. Nevertheless, approximately 70% of subjects chose it for the social contracts; virtually no one chose it for the matching descriptive rule.

years old" (Griggs and Cox, 1982; Cosmides, 1985). According to our computational theory, however, performance also should be high for unfamiliar ones—such as, "If a man eats cassava root, then he must have a tattoo on his face," where cassava root is portrayed as a highly desirable aphrodisiac, and having a facial tattoo is a sign of being married. As figure 87.2A shows, this is true. Subjects choose the *benefit accepted* card (e.g., "ate cassava root") and the *requirement not met* card (e.g., "no tattoo") for any social conditional that can be interpreted as a social contract and in which looking for violations can be interpreted as looking for cheaters (supports D1, D3, D7, D8; disconfirms B1; Cosmides, 1985, 1989; Gigerenzer and Hug, 1992; Platt and Griggs, 1993). Indeed, familiarity did not help at all. Cosmides (1985) found that performance was just as high on unfamiliar as on familiar social contracts—an uncomfortable result for any explanation that invokes domain-general learning, which depends on familiarity and repetition.

From a domain-general, formal view, investigating men eating cassava root and men without tattoos is logi-

cally equivalent to investigating people going to Boston and people taking cabs. But everywhere it has been tested (adults in the United States, United Kingdom, Germany, Italy, France, Hong-Kong, Japan; schoolchildren in Ecuador; Shiwi hunter-horticulturists in the the Ecuadorian Amazon (Sugiyama, Tooby, and Cosmides, 1995), people do not treat social exchange problems as equivalent to other kinds of reasoning problems. Their minds distinguish social exchange contents and reason as if they were translating these situations into representational primitives such as “benefit,” “cost,” “obligation,” “entitlement,” “intentional,” and “agent” (Cheng and Holyoak, 1985; Cosmides, 1989; Platt and Griggs, 1993; supports D13). Indeed, the relevant inference procedures are not activated unless the subject has represented the situation as one in which one is entitled to a benefit only if one has satisfied a requirement.

Do social contracts simply activate content-free logical rules?

The procedures activated by social contract rules do not behave as if they were designed to detect *logical* violations per se; instead, they prompt choices that track what would be useful for detecting cheaters, regardless of whether this happens to correspond to the logically correct selections. For example, by switching the order of requirement and benefit within the if-then structure of the rule (figure 87.3), one can elicit responses that are functionally correct from the point of view of cheater detection, but logically incorrect. Subjects choose the *benefit accepted* card and the *requirement not met* card—the adaptively correct response if one is looking for cheaters—no matter what logical category these cards fall into (figure 87.2B; supports D9, D8; disconfirms B2, B3, B1). This means that cheater detection is not accomplished by procedures embodying the content-free rules of logical inference. If it were, then subjects would choose the logically correct response—*P and not-Q*—even on switched rules, where these represent the *requirement met* card (P) and the *benefit not accepted* card (*not-Q*). Yet these represent people who cannot possibly have cheated. A person who has met a requirement without accepting the benefit this entitles one to is either an altruist or a fool, but not a cheater.

That content-free rules of logic are not responsible for cheater detection was demonstrated in a different way by Gigerenzer and Hug (1992) in experiments designed to test the prediction that what counts as cheating should depend on one’s perspective (D4, D5, B2, B4). Subjects were asked to look for violations of rules such as, “If a previous employee gets a pension from a firm, then that person must have worked for the firm

for at least 10 years.” For half of them, the surrounding story cued the subjects into the role of the employer, whereas for the other half, it cued them into the role of an employee.

If social contracts activate rules for detecting logical violations, then this manipulation should make no difference. Perspectives, such as that of employer versus employee, play no role in formal logic: To detect a logical violation, the *P* card (“employee got the pension”) and the *not-Q* card (“employee worked for less than 10 years”) should be chosen, no matter whose perspective you have taken. But in social contract theory, perspective matters. Because these two cards represent instances in which the employer may have been cheated, a cheater detection subroutine should choose them in the employer condition. But in the employee condition, the same cheater detection procedures ought to draw attention to situations in which an *employee* might have been cheated, that is, the “employee worked for more than 10 years” card (Q) and “employee got no pension” card (*not-P*). In the employee condition, *Q and not-P* is logically incorrect, but adaptively correct.

The results confirmed the social contract prediction. In the employer condition, 73% of subjects chose *P and not-Q* (which is both logically and adaptively correct), and less than 1% chose *Q and not-P* (which is both logically and adaptively incorrect). But in the employee condition, 66% chose *Q and not-P*—which is logically incorrect but adaptively correct—and only 8% chose *P and not-Q*—which is logically correct, but adaptively incorrect (supports D4, D7, D9; disconfirms B2, B4). Furthermore, the percent of subjects choosing the correct cheater detection response did not differ significantly in these two conditions (73% vs. 66%), indicating that it was just as easy for subjects to compute a cost-benefit representation from the perspective of the employer as from that of the employee (supports D5).

Are cheater detection procedures part of “general intelligence”?

Data from Maljkovic (1987) show that the ability to detect cheaters can remain intact even in individuals suffering large impairments in their more general intellectual functioning. Maljkovic tested the reasoning of patients suffering from positive symptoms of schizophrenia, comparing their performance to that of hospitalized controls. The schizophrenic patients were indeed impaired on more general tests of logical reasoning, in a way typical of individuals with frontal lobe dysfunction. But their ability to detect cheaters on Wason selection tasks was unimpaired (supports D1, D12; disconfirms

FIGURE 87.4 All social contracts are permission rules; all precaution rules are permission rules; but not all permission rules are social contracts or precautions. Many permission rules that have been tested fall into the white area (neither social contracts nor precautions): these do not elicit the high levels of performance that social contracts and precaution rules do. This argues against permission schema theory. By testing patients with focal brain damage and through priming studies, one can see whether reasoning about social contracts and precautions can be dissociated. These methods allow one to determine whether reasoning about social contracts and precaution rules is generated by one permission schema, or by two separate domain-specific mechanisms.

primitives of a permission schema have a larger scope than those of social contract algorithms. For example, a “benefit taken” is a kind of “action taken,” and a “cost paid” (i.e., a benefit offered in exchange) is a kind of “precondition satisfied.” They take evidence that people are good at detecting violations of precaution rules—rules of the form, “If hazardous action H is taken, then precaution P must be met”—as evidence for their hypothesis (on precautions, see Manktelow and Over, 1988, 1990). After all, a precaution rule is a kind of permission rule, but it is not a kind of social contract. We, however, have hypothesized that reasoning about precaution rules is governed by a functionally specialized inference system that differs from social contract algorithms and operates independently of them (Cosmides and Tooby, 1992, 1997; Fiddick, 1998; Fiddick, Cosmides, and Tooby, 1995; figure 87.4).

In other words, there are two competing proposals for how the computational architecture that causes reasoning in these domains should be dissected. Several lines of evidence speak to these competing claims.

ARE BENEFITS NECESSARY? According to the grammar of social exchange, a rule is not a social contract unless it contains a *benefit to be taken*. Transformations of input should not matter, as long as the subject continues to represent an action or state of affairs as beneficial to the potential violator and the violator as illicitly obtaining this benefit. The corresponding argument of the permission schema—an *action to be taken*—has a larger scope: Not

all “actions taken” are “benefits taken.” If this construal of the rule’s representational structure is correct, then the behavior of the reasoning system should be invariant over transformations of input that preserve it. But it is not. For example, consider two rules: (1) “If one goes out at night, then one must tie a small piece of red volcanic rock around one’s ankle” and (2) “If one takes out the garbage at night, then one must tie a small piece of red volcanic rock around one’s ankle.” Most undergraduate subjects perceive the action to be taken in (1)—going out at night—as a benefit, and 80% of them answered correctly. But when one substitutes a different action—taking out the garbage—into the same place in the argument structure, then performance drops to 44% (supports D6, D7; disconfirms B4, B6; Cosmides and Tooby, 1992). This transformation of input preserves the *action to be taken* representational structure, but it does not preserve the *benefit to be taken* representational structure—most people think of taking out the garbage as a chore, not a benefit. If the syntax of the permission schema were correct, then performance should be invariant over this transformation. But a drop in performance is expected if the syntax of the social contract algorithms is correct.

We have been doing similar experiments with precaution rules (e.g., “If you make poison darts, then you must wear rubber gloves.”). All precaution rules are permission rules (but not all permission rules are precaution rules). We have been finding that the degree of hazard does not affect performance, but the nature of the precaution does—even though all the *precautions taken* are instances of *preconditions satisfied*. Performance drops when the precaution is not perceived as a good safeguard given the hazard specified (Rutherford, Tooby, and Cosmides, 1996). This is what one would expect if the syntax of the rules governing reasoning in this domain take representations such as *facing a hazard* and *precaution taken*; it is not what one would expect if the representations were *action taken* and *precondition satisfied*.

DOES THE VIOLATION HAVE TO BE CHEATING? By hypothesis, social contract algorithms contain certain conceptual primitives that the permission schema lacks. For example, *cheating* is taking a benefit that one is not entitled to; we have proposed that social contract algorithms have procedures that are specialized for detecting *cheaters*. This conceptual primitive plays no role in the operation of the permission schema. For this schema, whenever the action has been taken but the precondition has not been satisfied, a *violation* has occurred. People should be good at detecting violations, whether that violation counts as cheating (the benefit has been illicitly taken by the violator) or a mistake (the violator does not get the benefit stipulated in the rule).

Given the same social contract rule, one can manipulate contextual factors to change the nature of the violation from cheating to a mistake. When we did this, performance changed radically, from 68% correct in the cheating condition to 27% correct in the mistake condition (supports D2; disconfirms B1-B6). Gigerenzer and Hug (1992) found the same drop in response to a similar context manipulation.

In bargaining games, experimental economists have found that subjects are twice as likely to punish defections when it is clear that the defector intended to cheat as when the defector is a novice who might have simply made a mistake (Hoffman, McCabe, and Smith, 1997). This provides interesting convergent evidence, using entirely different methods, for a conceptual distinction between mistakes and cheating, where intentionality also plays a role.

IS REASONING ABOUT SOCIAL CONTRACTS AND PRECAUTIONS GENERATED BY ONE MECHANISM OR TWO? If reasoning about social contracts and precautions is caused by one and the same mechanism—a permission schema—then neurological damage to this schema should lower performance on both rules equally. But if reasoning about these two domains is caused by two, functionally distinct mechanisms, then one could imagine neurological damage to the social contract algorithms that leaves the precaution mechanisms unimpaired, and vice versa. Stone and colleagues (Stone, Cosmides, and Tooby, 1996; Stone, Cosmides, and Tooby, forthcoming; Stone et al., 1997) tested R. M., a patient with bilateral damage to his orbitofrontal and anterior temporal cortex, as well as to the left amygdala, on social contract and precaution problems that had been matched for difficulty on normal controls (who got 71% and 73% correct, respectively). R. M.'s performance on the precaution problems was 70% correct: equivalent to that of the normal controls. In contrast, his performance on the social contract problems was only 39% correct. This is a marked impairment, whether compared to the normal controls or to his own performance on the precaution problems (figure 87.5). R. M.'s difference score—his percent correct for precautions minus his percent correct for social contracts—was 31 percentage points. In contrast, the difference scores for individual normal subjects were all close to zero (mean = 0.14 percentage points). If reasoning on both social contracts and precautions were caused by a single mechanism—whether a permission schema or anything else—then one would not be able to find individuals who perform well on one class of content but not on the other. This pattern of results is best explained by the hypothesis that reasoning about these

FIGURE 87.5 Performance of R.M. versus normal controls: precautions versus social contracts. Selective impairment of social contract reasoning in R. M., a patient with bilateral damage to the orbitofrontal and anterior temporal lobes and damage to the left amygdala. R. M. reasons normally when asked to look for violations of precaution rules but has difficulty when asked to look for (logically isomorphic) violations of social contracts (i.e., detecting cheaters). The y-axis plots the difference between R. M.'s percent correct and the mean performance of 37 normal controls. (Data from Stone, Cosmides, and Tooby, 1996.)

two types of content is governed by two separate mechanisms.

Although tests of this kind cannot conclusively establish the anatomical location of a mechanism, tests with other patients suggest that amygdalar damage was important in creating this selective deficit. Stone and associates tested two other patients who had no damage to the amygdala. One had bilateral orbitofrontal and anterior temporal damage; the other had bilateral anterior temporal damage, but no orbitofrontal damage. Neither patient exhibited a selective deficit; indeed, both scored extremely high on both classes of problems.

Convergent evidence for the single dissociation found by Stone and colleagues comes from a study by Fiddick and associates (Fiddick, Cosmides, and Tooby, 1995; Fiddick, 1998). Using a priming paradigm, they produced a functional dissociation in reasoning in normal, brain-intact subjects. Indeed, they were able to produce a *double* dissociation between social contract and precaution reasoning. More specifically, they found that: (1) when the problem used as a prime involved a clear social contract rule, performance on the target problem—an ambiguous social contract—increased. Moreover, this was due to the activation of social contract categories, not logical ones: when the prime was a switched social contract, in which the correct cheater

detection answer is *not* the logically correct answer (see figure 87.3), subjects matched their answers on the target to the prime's benefit/requirement categories, not its logical categories. (2) When the prime was a clear precaution rule, performance on an ambiguous precaution target increased. Most importantly, (3) these effects were caused by the operation of two mechanisms, rather than one: the precaution prime produced little or no increase in performance on an ambiguous social contract target; similarly, the social contract prime produced little or no increase in performance on an ambiguous precaution target.

This should not happen if permission schema theory were correct. In that view, it should not matter which rule is used as a prime because the only way in which social contracts and precautions can affect the interpretation of ambiguous rules is through activating the more general permission schema. Because both types of rules strongly activate this schema, an ambiguous target should be primed equally by either one.

Conclusion

Many cognitive scientists believe that theories of adaptive function are an explanatory luxury—fanciful, unfalsifiable post-hoc speculations that one indulges in at the end of a project, after the hard work of experimentation has been done. Nothing could be farther from the truth. By using a computational theory specifying the adaptive problems entailed by social exchange, we and our colleagues were able to predict, in advance, that certain very subtle changes in content and context would produce dramatic differences in how people reason. Without this theory, it is unlikely that this very precise series of effects would have been found. Even if someone stumbled upon a few of them, it is unlikely that their significance would have been recognized. Indeed, the situation would be similar to that in 1982, when we started this work: cognitive scientists could not understand why some familiar content—such as the drinking-age problem—produced “logical” reasoning whereas other familiar content—such as the transportation problem—did not (Griggs and Cox, 1982). By applying the adaptationist program, we were able to explain what was already known and to discover design features that no one had thought to test for before.

To isolate a functionally organized mechanism within a complex system, one needs a theory of what function that mechanism was designed to perform. The goal of cognitive neuroscience is to dissect the computational architecture of the human mind into functional units. The adaptationist program is cognitive neuroscience's best hope for achieving this goal.

NOTE

1. Its relative rarity also suggests that this machinery is unlikely to evolve unless certain other cognitive capacities—components of a theory of mind, perhaps—are already in place.

Introduction

DANIEL L. SCHACTER

Human consciousness is just about the last surviving mystery.
—*Daniel C. Dennett (1991)*

Every period in the relatively brief history of neuroscience has considered that it had a special, sometimes even ultimate, insight into the neural mechanisms of conscious awareness. . . .
—*Lawrence Weiskrantz (1991)*

Mention the term “consciousness” to a cognitive neuroscientist, and you will probably elicit one of two very different reactions. Some will likely shrug or groan, mumbling uncomfortably that consciousness is a construct that we do not yet know how to approach sensibly or to investigate productively. Dennett (1991, p. 21) acknowledged the vexing “mystery” of consciousness: “A mystery is a phenomenon that people don’t know how to think about—yet.” Others, however, will probably respond with enthusiasm, even excitement, citing the latest experimental dissociations between conscious and unconscious processes in neuropsychology or electrophysiology as evidence that cognitive neuroscience is on the verge of finally “cracking” the riddle of consciousness. Weiskrantz (1991, p. 1) has noted that this enthusiasm is not without historical precedent.

Consciousness is a particularly challenging topic for cognitive neuroscience. The challenge begins with the fact that most investigators have a difficult time agreeing on an adequate definition of the term (e.g., Wilkes, 1988). Contemporary treatments of consciousness often begin with an acknowledgment that although we all have a subjective sense of what we mean when we use the expression, satisfactory formal definitions are difficult to come by. Indeed, a number of writers have argued that the term “consciousness” is simply too coarse to be useful theoretically. Block (1995), for instance,

distinguished between “phenomenal consciousness” (the raw “feel” of experience) and “access consciousness” (the accessibility of experience to verbal report and use in intentional control), claiming that various analyses of consciousness run into difficulty because they fail to make such a distinction. Tulving (1985) had previously distinguished among three types of consciousness: *anoetic* (nonknowing), which entails simple awareness of external stimuli; *noetic* (knowing), which involves awareness of symbolic representations of the world; and *autonoetic* (self-knowing) consciousness, which involves awareness of self and personal experience extended in time. Farthing (1992) offered a distinction between primary consciousness—simple perceptual awareness of external and internal stimuli—and reflective consciousness—“thoughts about one’s own conscious experiences *per se*” (1992, p. 13). Natsoulas (1978) distinguished among seven different ways in which the term “consciousness” has been used, and numerous other distinctions among forms or types of consciousness could be cited (cf. Chalmers, 1996; Marcel and Bisiach, 1988; Milner and Rugg, 1991; Weiskrantz, 1997).

Definitional problems notwithstanding, cognitive neuroscientists have approached phenomena of consciousness from a variety of perspectives. During the 1950s and 1960s there was great excitement about possibilities for understanding the neurophysiological basis of “states” of consciousness, spurred on by the groundbreaking discoveries by Moruzzi and Magoun (1949) concerning the reticular activating system and conscious awareness, and stimulated by the discovery of rapid eye movement sleep (Aserinsky and Kleitman, 1953). A new and startling perspective on consciousness was provided by observations of commissurotomy, or split-brain, patients that began to appear in the 1960s and 1970s. Led by such investigators as Sperry (1966), Bogen (1969), and Gazzaniga (1970), studies of split-brain patients produced striking observations that suggested the possible existence of independent systems of consciousness in each hemisphere. These observations provided fertile ground for theorizing about consciousness—much of it rather speculative—in neuroscience, psychology, and philosophy (cf. Popper and Eccles, 1977; Puccetti, 1981; Springer and Deutsch, 1985).

While much of the initial excitement surrounding split-brain studies developed during the 1960s and early 1970s, a different sort of phenomenon began to capture the attention of cognitive neuroscientists during the late 1970s and 1980s: Demonstrations that various kinds of brain-damaged patients exhibit preserved access to non-conscious or implicit knowledge despite a profound impairment of conscious or explicit knowledge. Perhaps

the best known and most arresting example is that of blindsight, where patients with lesions to striate cortex who deny conscious perception of visual stimuli nonetheless can “guess” their location and other attributes (e.g., Weiskrantz, 1986, 1997). Similarly, amnesic patients who lack explicit or conscious memory for their recent experiences can exhibit nonconscious or implicit memory for aspects of those experiences, as exemplified by such phenomena as priming and skill learning (Schacter, 1987). Similar kinds of dissociations have been observed in patients with aphasia, alexia, and unilateral neglect, among others (Schacter, McAndrews, and Moscovitch, 1988), and have led to the discovery of analogous phenomena in normal subjects (for recent reviews, see Schacter and Buckner, 1998; Stadler and Frensch, 1997). These dissociations have led to a variety of proposals concerning the nature, function, and neural basis of consciousness (see Milner and Rugg, 1991).

The 1980s also witnessed renewed attention to another neuropsychological phenomenon with important implications for thinking about consciousness: unawareness of deficit, or *anosognosia*. The observation that some brain-damaged patients claim to be entirely unaware of the existence of deficits that are all too obvious to others was first reported in the late nineteenth and early twentieth centuries. Unfortunately, implications of the phenomenon for understanding the nature of conscious experience were not pursued systematically, perhaps because of the prevalence of psychodynamic approaches to the issue (for historical review, see McGlynn and Schacter, 1989). However, stimulated largely by the pioneering research of Bisiach and his colleagues concerning *anosognosia* in neglect patients (Bisiach and Geminiani, 1991), the central importance of *anosognosia* and related phenomena for theories of consciousness has come to be more widely appreciated (see Prigatano and Schacter, 1991, and more recent work by Ramachandran, 1995, 1998, for an overview of contemporary approaches).

With the rapid development of functional neuroimaging during the 1990s, we are beginning to witness the first applications of imaging technologies to consciousness-related issues, ranging from nonconscious aspects of perception (Sahraie et al., 1997; Whalen et al., 1998) to the development of automatic habits (Raichle et al., 1994) and distinctions among conscious and nonconscious forms of memory (Schacter et al., 1996; Squire et al., 1992). Although the use of neuroimaging to understand problems related to consciousness is just beginning, we can expect many more such studies in the future.

The chapters in this section provide a broad overview of approaches to consciousness in contemporary cognitive neuroscience that summarize in some depth the

foregoing areas of investigation, and point the way to future research. The first two chapters focus on general conceptual and methodological issues. Güzeldere, Flanagan, and Hardcastle provide a philosophical treatment of various constructs that are central to discussions of consciousness, using the compelling phenomenon of blindsight as a “test case” to develop and explore their views concerning alternative philosophical approaches to consciousness. Koch and Crick consider fundamental aspects of visual consciousness and describe the logic of an approach that postulates the existence of a specific consciousness system. Merikle and Daneman focus on the ways in which consciousness and awareness have been defined and operationalized in studies of conscious vs. nonconscious perceptual functions. They examine a general distinction between “subjective” and “objective” criteria for distinguishing conscious from unconscious perception, and argue for the usefulness of focusing on qualitative differences between conscious and unconscious processes. These points have important implications for consciousness studies in general—implications that extend beyond the domain of perceptual functions treated in their chapter.

The subsequent chapters also address general conceptual and methodological issues in the context of more focused discussions of specific phenomena that are critical to the analysis of consciousness. Raichle outlines a research strategy in which functional neuroimaging is used to understand the nature of brain activity as people become increasingly practiced at carrying out various kinds of cognitive and motor tasks. Because these increasingly automatic functions make correspondingly fewer demands on conscious processes, studying them with functional neuroimaging can provide a potentially important window on particular aspects of consciousness. Knight and Grabowecy focus on the role of frontal regions in conscious experience, using both neuropsychological and electrophysiological observations to formulate a general perspective on the issue. They emphasize the crucial importance of various frontal regions for aspects of consciousness that are related to time—planning into the future and remembering back to the past. Baynes and Gazzaniga summarize and integrate numerous observations concerning consciousness and the cerebral hemispheres, including some striking new phenomena observed in split-brain patients that raise intriguing questions concerning the nature of consciousness in the cerebral hemispheres. They discuss these phenomena with respect to the notion of a left-hemisphere “interpreter” that plays a key role in generating aspects of conscious experience.

Hobson, Pace-Schott, and Stickgold consider problems of consciousness with respect to sleep and alterations in

arousal. They approach issues of sleep and consciousness from the perspective of contemporary cognitive neuroscience, suggesting explicit linkages between underlying neurophysiology and conscious experience during sleep. Hobson and colleagues summarize a new wave of recent studies that have used functional neuroimaging techniques to explore brain involved with aspects of conscious experience during sleep and dreaming.

As we enter the twenty-first century, are scientists any closer to understanding consciousness than those of the preceding century? Only time will tell, but the ferment of activity surrounding the topic can at least assure us that the age-old enigma of consciousness will continue to occupy cognitive neuroscientists well into the new millennium.

The Nature and Function of Consciousness: Lessons from Blindsight

GÜVEN GÜZELDERE, OWEN FLANAGAN, AND VALERIE GRAY HARDCASTLE

ABSTRACT It is not easy to explain why consciousness exists or should exist. What does consciousness add to an intelligent system that high-performance information processing, storage, and retrieval capabilities don't? Blindsight, which is interesting both biologically and philosophically, is a phenomenon that brings to the fore questions about the role consciousness plays in our general cognitive economy. In this chapter, we discuss the much-debated topic of the function of consciousness in the light of blindsight, pointing out some of its implications for thinking about the nature of consciousness.

In 1866, the English biologist T. H. Huxley remarked, "What consciousness is, we know not; and how it is that anything so remarkable as a state of consciousness comes about as the result of irritating nervous tissue, is just as unaccountable as the appearance of the Djinn when Aladdin rubbed his lamp in the story" (Huxley, 1866, p. 193). In 1999, many in the natural sciences and philosophy would scarcely disagree with Huxley, even though the geography of the dialectical space is more complicated today. Following a brief overview of some major philosophical positions on consciousness, this chapter focuses on a particular phenomenon—blindsight—to demonstrate how philosophical, psychological, and neuroscientific debates on the nature and function of consciousness can find a common platform for a fruitful exchange. (For a detailed "field guide" to the consciousness literature, see Güzelde, 1997.)

Francis Crick and Cristof Koch (1990) called consciousness "the most mysterious aspect of the mind-body problem." What is the nature of this mystery? For some, consciousness is mysterious because it seems to have no place for the realm of physical magnitudes (Nagel, 1974, 1986). For others, consciousness is a natural phenomenon realized in biological systems, just as other biological and psychological phenomena are, but the na-

ture of the relation between consciousness and its bodily underpinnings is bound to elude us forever. This is so because we human beings do not have the requisite cognitive capacities for reaching a full understanding of the mind-body problem epitomized by the problem of consciousness (McGinn, 1991).

These are related, but different positions. In the first line of reasoning, there is something inherently unique about the nature of consciousness that makes it different from all other kinds of physical, biological, or psychological phenomena. Thus, even an advanced science of the mind may never be able to explain consciousness in the same way chemistry explained the atomic structure of matter or biology explained the genetic structure of life. In the second line of reasoning, on the other hand, consciousness does not differ *in kind* from other biological and psychological phenomena. However, a scientific account of consciousness may be much more complicated than anything science has tackled thus far—so complicated, in fact, that the human mind will never be able to conquer it, even as cognitive reach of nonhuman animals will never stretch to an explanatory account of the motions of heavenly bodies.

Consciousness skeptics occupy yet a third position, suggesting that the term *consciousness* may be no more than a "dummy-term like 'thing' with no specific content" (Wilkes, 1984), in which case it should be discarded from the scientific and philosophical vocabulary. Or consciousness may be no more real than a scientifically defunct ghostly entity, in which case one would have good reasons for "doubting that oneself is conscious . . . and [thus] thinking that nothing is conscious" (Rey, 1988).

Many others, abjuring skepticism and mystery alike, have labored to develop various constructive explanatory accounts of consciousness. This group can be characterized by a common ontological denominator, say, a commitment to a materialist/naturalist framework; but here, too, we find differences of opinion. Consciousness is explained in terms of causal/functional roles (Lewis, 1966; Lycan, 1987), representational properties (Dretske, 1995; Tye, 1995), emergent biological properties

FIGURE 88.1 The primary visual pathway. This schematic illustrates the major projections from the retina, as viewed from the underside of the brain. The optic nerve connects retinal cells to the optic tract. The optic tract projects onto the lateral geniculate nuclei. Optic radiations from the lateral geniculate nucleus terminate in primary visual cortex, also known as area V1 or the striate cortex. Lesions in V1 result in the phenomenon of blindsight.

(Flanagan, 1992; Searle, 1992), higher-order mental states (Armstrong, 1980; Rosenthal, 1997), or computer-related metaphors (Dennett, 1991), or a combination of these.

Within this latter group, we find a certain group of philosophers characterized by an emerging commitment to a particular methodological strategy, a commitment shared by some psychologists and neuroscientists interested in explaining the nature and function of our subjective experiences. Research into the nature and function of consciousness has made some recent advances, especially in the field of cognitive neuroscience, on the basis of a triangulation of data coming from the phenomenological reports of patients, psychological testing at the cognitive/behavioral level, and neurophysiological and neuroanatomical findings. Churchland (1986) calls this strategy for studying the mind the “co-evolutionary strategy”; and Shallice (1988), Dennett (1978, 1991), and Flanagan (1985, 1991, 1992) each promote co-evolutionary methodologies that attempt to bring into equilibrium the phenomenological, the psychological, and the neurobiological in understanding the mind.

Here, using blindsight as an example, we present one way in which this methodology can be used to further our understanding of consciousness. Blindsight is one of the more curious deficits studied in cognitive neuroscience. Lesions in the primary visual cortex (V1) were thought to result in complete blindness. This was reasonable, as V1 was considered to be the terminal information processing station along the primary visual pathway that solely subserved vision (see figure 88.1). However, Weiskrantz and Cowey (1967) pointed out that monkeys whose striate cortex had been removed acted in some

ways as if they could see. These monkeys interacted with their environment in a fluid manner unexpected of completely blind animals. Similar effects are observed in humans, with an interesting twist. Patients with primary visual cortex damage complain that they are blind—that they lack visual experiences—in the field corresponding to the lesioned area. However, upon closer examination, it appears that they can make certain visual discriminations, despite protests that they can see nothing in their blindfield.

Since the publication of Pöppel, Held, and Frost’s initial findings on residual visual function in four war veterans with cortical damage (1973), neuroscientists have been documenting the degree to which blind people can react to visual stimuli and trying to explain how they do so. Weiskrantz and colleagues (1974) coined the term “blindsight” for the phenomenon. And since then, its study (and related sensory deficits dubbed, similarly oxymoronic, “numb-sense” and “deaf-hearing”) has been a thriving industry in neuroscience (cf. Weiskrantz, 1986, 1997).

Philosophers picked up on blindsight relatively soon after its discovery—though blindsight-type thought experiments had already anticipated the phenomenon (cf. Perkins, 1971). Mellor (1977) introduced blindsight into the literature when he noted, correctly, that blindsight represents an actual case in which function and experience come apart to some degree. Thus, he raised prospects for neuroscientific and philosophical cooperation on questions about the accuracy of first-person psychological reports, about the possibility—indeed the actuality—of nonconscious information-bearing states, and about the function of consciousness. Following Searle (1979) and Churchland (1980), the practice of using blindsight as a case study in discussions of consciousness, perception, and intentionality has become a lively pocket of philosophical literature as well (Güzeldere, 1998).

Blindsight is interesting, first and foremost, because it shows how visual function and visual experience can diverge, at least to some extent, in defiance of ordinary experience. It is a matter of common faith in cognitive neuroscience that not all cognitive processing is conscious. But it is no easy task to separate how unconscious and conscious processing systems divide mental labor. Investigating blindsight gives us one way of investigating the particular causal mechanisms that underlie conscious visual processing. More specifically, understanding blindsight is key to understanding alternative notions of visual capacities: Whether visual capacities are subserved solely by the primary visual pathway in which the primary visual cortex plays an indispensable role, so that all visual discriminations are made con-

sciously; or whether certain visual functions are subserved by multiple pathways radiating toward various other cortical and subcortical areas in addition to V1 via different routes, so that some visual discriminations may be made unconsciously.

In this context, blindsight offers an actual example of what the dissociation of function and experience can be like—a thought experiment “made flesh.” As such, blindsight promises new progress on questions of perennial concern to philosophers, psychologists, and neuroscientists. To what extent are we aware of the information received which affects performance? To what extent is performance consciously controlled? Is consciousness a particular component in the system of mental life, or is it a more general feature of the workings of the system? Does consciousness *necessarily* play a role in mental life, or could we do just as well without it?

Blindsight research

Continuing research for the past 25 years has considerably expanded our understanding of the scope of the residual functions present in cortically damaged blindsight patients, from spatial localization of visual targets in the field defect to spectral discrimination, to discrimination of form and movement. In addition, blindsight effects are also measured indirectly: The indirect tasks make use of the fact that visual stimuli falling in the field defect, while not noticeable or reportable by the subject, affect the subject’s response to subsequent stimuli presented in the normal visual field. For example, light flashed in the blindfield speeds the reaction time to visual stimuli presented in the normal field (Marzi et al., 1986); words presented in the blindfield semantically prime word pairs in the normal visual field (Marcel, 1983); and figure-halves presented in the blindfield complete other figure-halves presented in the normal visual field (Marcel, as reported in Weiskrantz, 1990).

It is important to emphasize that blindsight patients in these studies do not perform as well as normal subjects on visual tasks. In all of these tasks, the patients are presented with a small set of relatively simple stimuli. They fail to discriminate more complex or subtle phenomena in any fashion. Furthermore, patients never initiate localization- or discrimination-related behavior themselves in the complete absence of consciousness of visual stimuli in their blindfield. Nevertheless, the residual visual capacities that remain comprise an impressive array of capacities exhibited by patients who paradoxically insist that they cannot see.

The first question to address is whether these capacities are residual of a damaged but nonetheless partially functioning primary visual pathway, or whether they

FIGURE 88.2 Alternate visual pathways. Evidence suggests that retinal information not only travels to V1 via the lateral geniculate nuclei (LGN), but also goes to extrastriate cortex via the superior colliculus and the pulvinar, or perhaps via the superior colliculus alone. It is also possible that there are some connections from LGN directly to extrastriate cortex, skipping V1 entirely.

provide evidence for alternative pathways for the visual system. Discovering the answer to this question would tell us something about the nature of visual consciousness vis-a-vis visual function. If losing part of our primary visual pathway means that we lose consciousness, then consciousness is likely to be a threshold effect. Without enough activation, we are not conscious of whatever information is being processed. If our primary visual pathway is completely disrupted and visual processing continues only subcortically, then consciousness might be area-specific. In particular, this would show that we need V1 to be conscious—other visual areas won’t suffice. These two possibilities are not mutually exclusive, but knowing the details of the physiology underlying blindsight will give us clues about where to expend our research energy.

Whether the primary visual pathway is necessary for vision, and whether blindsight is a counterexample to this hypothesis, has been a puzzle for neuroscience. And the answer is not uncontroversial. Some have argued that residual functions in blindsight may all be attributable to methodological artifacts, such as the scattering of light onto the intact parts of the retina during the visual presentations (Campion, Lotto, and Smith, 1983). Another hypothesis is that thus far unnoticed islands of spared cortical tissue are responsible for the blindsight patients’ discriminatory abilities (Fendrich et al., 1992; Gazzaniga, Fendrich, and Wessinger, 1994; cf. Barinaga, 1992). On the other hand, there are a number of radiations from the retina that extend to regions other than the striate cortex (see figure 88.2). For example, there are thalamic routes to the extrastriate cortex, via the superior colliculus and the pulvinar, as well as routes to subcortical areas (in monkeys) via the collicular route plus the accessory optic tract (Hernandez-Gonzalez and Reinoso-Suarez, 1994; Webster et al., 1993). These different pathways could subserve the residual capacities exemplified in blindsight as the absence of a properly functioning

primary visual pathway “presses them into action” (Weiskrantz, 1997).

Final resolution of the debates in the neurophysiology of blindsight will require more data and further studies. At present, the competing hypotheses regarding alternative pathways that mediate the residual visual functions in blindsight patients are under investigation, and the jury is still out on the definitive verdict on the neurological mechanism of blindsight.

Implications for consciousness studies

Philosophers and scientists have approached blindsight primarily as an actual example of a mental phenomenon where functional aspects come apart from experiential aspects. This issue has a significant place in philosophy of mind and cognitive science owing to deep-rooted debates about the function of consciousness and the possibility of *epiphenomenalism*—the view that consciousness is just a causally inert by-product, much like, in T. H. Huxley’s words, the steam of a steam engine with respect to the workings of the locomotive. There have also been some skeptical voices among philosophers who claimed that blindsight data should count for little in the debates concerning the nature and function of qualitative experience. To these issues we now turn.

THE FUNCTION OF CONSCIOUSNESS How is blindsight used in support of various theories of consciousness? Mainly, to support two claims: Consciousness facilitates our interpretation and comprehension of the world around us; and consciousness makes behavior more adaptive.

Blindsight patients claim to have no information about the goings-on in their blindfield. They are wrong in this, but we have to press them to get them to show what information they actually have. The case is altogether different with normal persons, and Flanagan (1992) argues that this difference is crucial from a functional point of view. Conscious awareness of a word that favors a particular interpretation, e.g., *river* bank over money *bank*, leads to better performance on disambiguation tasks than does the cruder sensitivity to the helpful clue in blindsight (see also Hardcastle, 1995; Vaina, 1995). The suggested conclusion here is that being conscious helps us process semantic information.

In addition, conscious awareness of objects in our environment contributes to voluntary action. The blindsighted person will make no move toward objects in his or her blindfield. Nonetheless, under forced-choice conditions, the blindsighted exhibit intriguing behavior. As Marcel reports, “Cortically blind patients who have no phenomenal experience of an object in the blindfield

will nonetheless preadjust their hands appropriately to size, shape, orientation and 3-D location of that object in the blindfield when forced to attempt to grasp it. Yet such patients will make no spontaneous attempt to grasp a glass of water in their blind field even when thirsty. Voluntary actions often depend upon conscious perception” (Marcel, 1986, p. 41). This sort of evidence implies that conscious awareness of the environment also facilitates adaptive motor actions in creatures like us: “Information needs to be presented to us phenomenally for it to play a role in the choice, initiation, or direction of the intentional action” (Van Gulick, 1994, p. 33).

Van Gulick (1994) notes that this conclusion makes most sense if we assume that consciousness is a form of self-awareness in that we are consciously aware of objects only in relation to ourselves (see also Searle, 1983). My experience of my computer is as *my* computer in front of *me* which *I* am currently using in *my* world. Representing information in terms of how it affords us opportunities to move about or interact in our world makes it easily available to guide our actions in pursuit of our goals.

While this kind of reasoning about the function of consciousness seems too obvious to belabor, the issue vis-à-vis blindsight is not as clear as it might appear at first blush. Some philosophers suggest that since blindsight patients demonstrate both implicit semantic priming and pattern completion in a blindfield, the exact contribution of consciousness to the comprehension of word meaning, object recognition, and the initiation of action remains unclear. If blindsight patients can be trained to learn to act on the visual cues in their blindfield on their own, as Block (1995) suggests, they can become living examples of agents whose visual capacities remain entirely instantiated independently of their consciousness. This would show that visual consciousness is not necessary in the instantiation of visual function.

Note, however, that the performance of blindsight patients is always very limited, confined to simple tasks under forced-choice laboratory conditions. Thus, blindsight patients remain essentially impaired in their abilities to do in their blindfield what normally sighted patients can do. The fact that repeated exposures to the same visual stimuli has produced no blindsight patient who could act voluntarily on an unrestricted set of visual cues in the blindfield provides some evidence that visual consciousness is tied to visual function.

There is another possibility to consider. The egg may stick to the pan for want of heated butter, but butter isn’t a necessary condition for nonstuck eggs. A Teflon pan will do. Might this be the case with consciousness? Blindsight patients are unaware of what is in their blindfield. It may be that imperfect performance is due to

lack of awareness; but it may also be that whatever knocks out awareness also degrades performance, not that awareness is necessary for optimal performance. That is, awareness of visual stimuli may be related to behavioral performance toward those stimuli not directly, but only by means of a common cause.

These sorts of worries should not be trivialized, and we have to wait for further empirical evidence for definitive answers. Nevertheless, inference to best explanation from the data in hand suggests that consciousness has a crucial role in the initiation of voluntary actions and plasticity of behavioral performance. Whatever else consciousness may be discovered to add to our cognitive economy, the incoming evidence from blindsight continues to give us a valuable, albeit small, piece of that puzzle.

EPIPHENOMENALISM AND ZOMBIES Some philosophers take the residual capacities of blindsight patients very seriously, claiming that blindsight can potentially show that consciousness plays no role in cognition. We could be exactly the same as we are now, only lacking in conscious experience. The theoretical possibility of beings who are like humans in every behavioral and functional aspect except for the fact that they lack experience (dubbed “zombies”) occupies a substantial space in contemporary philosophical literature. If this possibility is genuine, then consciousness is not necessary for intelligent life, hence one route to epiphenomenalism. And what can better show that such a possibility is indeed genuine than an actual case discovered by neuroscientists?

Some theoreticians have made claims along these lines, citing works on blindsight in support of the idea of epiphenomenalism. The earlier accounts suggest that because blindsight patients can show appropriate behaviors toward stimuli in their blindfields, we may conclude that consciousness plays no interesting causal role in our psychological life (Carruthers, 1989; see also Siewert, 1993). Later accounts, recognizing that blindsight patients are not as competent as normals in their behavior toward stimuli, maintain that the disability is not due to a lack of phenomenal consciousness, but to some other processing failure instead (Velmans, 1991).

Van Gulick (1994) remarks that epiphenomenalism is an implausible and unduly pessimistic position. We agree. The fact that conscious experience is regularly connected with certain abilities that blindsight patients lack is a fact that needs to be explained. There are numerous cases of neuropsychological deficits linked with deficits in consciousness, and in many of these cases the incapacitation of subjective awareness stands out as an explanatory factor. The simplest and most straightforward explanation of why blindsight patients cannot

perform certain tasks is that they are not visually conscious of all the things that normally sighted people are. While epiphenomenalism might be a logical possibility, it has no empirical plausibility in explaining blindsight in the face of what we learn from cognitive neuroscience (Flanagan, 1992; Hardcastle, 1995; Tye 1993, 1995).

Part of the appeal of epiphenomenalism lies in how one ranks different types of evidence. We support a method of seeking reflective equilibrium among all relevant data—no datum, phenomenological, psychological, or neuroscientific, automatically trumps the rest. This method has not always been employed in the history of the science of the mind, nor is it always used today. At the turn of the century, when introspectionism reigned in psychology, first-person phenomenology was privileged. Later, with behaviorism, behavioral evidence ruled, and phenomenology was considered something of an embarrassment. Later still (in the late 1970s and early 1980s), brain circuits and brain chemistry trumped when eliminative materialism had its fifteen minutes of fame. But dismissing first-person reports of subjective experience and discounting performance data from psychology could lead one to the mistake of looking exclusively for alternative nonconscious processing routes. Instead, consciousness should be taken seriously as an important phenomenon to be explained in its own right, a phenomenon that plays an important explanatory role in our cognitive economy.

SKEPTICAL REACTIONS Several philosophers have discussed the possibility that patients with blindsight might be conscious of information arriving through the scotoma, despite their inability to report what the data are (Block, 1995; Chalmers, 1996; McGinn, 1991; Mellor, 1977; Wider, 1993). Ned Block’s skeptical discussion advancing the possibility that blindsight patients may be, contrary to popular opinion, conscious of what is in their blindfield while lacking access to it for action or reportability is the most developed. Block bases his argument on the observation that the concept of consciousness is a mongrel and that not everyone means the same thing by the term. In particular, he distinguishes between “phenomenal” (P) consciousness and “access” (A) consciousness. P-consciousness refers to “the way it feels to have experiences, the qualitative character of experience.” A-consciousness, in contrast, refers to mental states that can be used as a premise in reasoning or the rational control of action, including verbal reports.

Block (1995) charges those who use blindsight as evidence that consciousness has a performance-enhancing function (e.g., Farah, 1994; Flanagan, 1992; Marcel, 1986; Schacter, 1989; Schacter, McAndrews, and

Moscovitch, 1988; Van Gulick, 1994) of reasoning in the following way:

1. In blindsight patients, consciousness of the stimuli in the blindfield is missing.
2. As a result, blindsight patients fail to engage in some expected behavior.
3. Therefore, consciousness has the function of (or plays a causal role in) bringing about that behavior.

This inference (dubbed “target reasoning”) is fallacious, Block claims, because it misses the distinction between the phenomenal and the access aspects of consciousness. Indeed, he claims that consciousness is used in one sense in the first premise and in the other sense in the conclusion. Examined more carefully the argument would look like this:

1. In blindsight patients, A-consciousness of the stimuli in the blindfield is missing.
2. As a result, blindsight patients fail to engage in some expected behavior.
3. Therefore, P-consciousness has the function of (or plays a causal role in) bringing about that behavior.

Put this way the argument is clearly invalid. According to Block it is A-consciousness that is missing in the blindsight patients, whereas the conclusion is drawn with regard to P-consciousness. Block claims that there is good evidence that A-consciousness plays a role in guiding voluntary action, whereas the (causal) status of P-consciousness remains entirely unclear. Any conclusion regarding P-consciousness based on this reasoning will be fallacious.

The validity of Block’s fallacy charge, and other arguments like it, depends on, among other things, whether he is entitled to divide the concept of consciousness into his two types: A-consciousness and P-consciousness. One can agree that the concept of consciousness is not a perfectly well-defined term while denying that there is any notion of consciousness that does not involve P-consciousness. To put it another way, whatever we mean by consciousness, we mean a state that has phenomenal feel. This renders Block’s A-consciousness, which isolated from any phenomenological feel, suspect as a concept of consciousness.

Ordinary usage supports this response to Block, as does common usage among those working on problems of consciousness. This includes those whom Block accuses of the fallacious “target reasoning,” who deny that there is any useful independent concept of A-consciousness (Flanagan, 1992; Graham, 1995). In a telling remark, Block acknowledges that A-consciousness without P-consciousness is “conceptually possible” but “perhaps not actual.” The concept of consciousness, no matter

how loosely defined, is used to name a familiar phenomenon, not a mere conceptual possibility. Again, the idea that there exists in the minds of those working in consciousness studies a concept of consciousness that is merely conceivable, and equally applicable to zombies, is worthy of suspicion.

Another problem with the A-consciousness/P-consciousness distinction presents itself in the reverse direction, in the implicit assumption that Block’s P-consciousness (by itself) captures the notion of phenomenal consciousness commonly used by Block’s target authors. But this assumption is false. The notion that phenomenal consciousness employed in target reasoning is typically laden with properties that belong to Block’s A-consciousness; and this, too, makes the A-consciousness/P-consciousness distinction unacceptable from the beginning (cf. Güzeldere and Aydede, 1997; Harman, 1995; Kobes, 1995; Mangan, 1997).

Consider, for example, Marcel, whose “phenomenal consciousness” includes “more than qualia”; it is what “we refer to as known directly or non-inferentially when we report our states” (Marcel, 1988). Thus, for Marcel, it seems that a P-conscious state must involve elements of A-consciousness in Block’s sense, e.g., availability to the subject for action. Similarly, Schacter uses the term “phenomenal consciousness” to mean “an ongoing awareness of specific mental activity . . . expressed knowledge that subjects are phenomenally aware that they possess” (Schacter, 1989, p. 356). Again, in Schacter’s terms, phenomenal consciousness involves the sort of cognitive elements that belong to Block’s A-consciousness, most notably verbal expressibility. In short, decoupling P-consciousness from A-consciousness in the way Block does goes against the intuitions that underlie the ordinary understanding of consciousness, and makes his two-type theory of consciousness stray from the one with which the target reasoning is operating.

Both the skeptics and the champions of the target reasoning think that blindsight patients possess some sort of information that drives their behavior in a certain way—making correct guesses in forced-choice situations, for example—even though they are not aware of possessing this information. According to Block, the patient’s awareness of (the possession of) such information, or its lack thereof, is a matter of A-consciousness, not P-consciousness.

In contrast, according to us, and to others who maintain that blindsight is useful for understanding consciousness, the patient’s (lack of) awareness of the information about the properties of the visual stimuli in her blindfield is a matter of P-consciousness. The problem is that what is being referred to as “P-consciousness” in arguments connecting blindsight to consciousness essentially in-

volves some sort of “ongoing access” to the phenomenal properties of the state one is in—an “immediately present availability.” In the case of humans, this becomes co-extensive with reportability under normal circumstances (but see Cam, 1985; Nelkin, 1993, 1995; Stoerig, 1997). To put the matter in another way, from our perspective, it is never the case that one is simultaneously P-conscious of certain qualities, while not “accessing” them—e.g., knowing about or being able to report their presence. In sum, when it comes to consciousness, *esse* has to be, if not *percipi*, then at least “access-related.”

This is not the case for the skeptics like Block. For that reason, however, they cannot claim, as they want to do, to subscribe to an uncontroversial, common-sense conception of consciousness, and at the same time maintain that a person can have phenomenal consciousness while resolutely denying that she is having any sense experience. The notion of qualitative character is supposed to capture the ways things seem to us—not necessarily the way things actually are, but their “seemings.” The skeptics’ insistence that one can have seemings without anything seeming (or, seeming to seem, if you like) a certain way goes against the grain of subjective experience.

The information the blindsight patient is sensitive to may be degraded because only tiny islands of processing remain in V1. This may be part of the reason the blindsight patient lacks phenomenal awareness. Or it may be that the information is not degraded but is simply untransmissible to a consciousness-related “module” due to visual information traveling only subcortically. This may be the reason why the blindsight patient has no consciousness of this information. Regardless of whether consciousness is location-dependent or dependent upon the degree of activity, the inference to the best explanation is that if the information were to become conscious, performance would improve. By what we know from the knowledge-without-awareness literature and about what the blindsight patient has access to, we should infer that the lack of conscious awareness of the blindfield partly explains the inability to bring the knowledge the system possesses into normal, high-quality play in inference, reporting, and action.

89 Some Thoughts on Consciousness and Neuroscience

CHRISTOF KOCH AND FRANCIS CRICK

ABSTRACT We outline our approach to the problem of consciousness by focusing on the neuronal correlate of visual awareness in the primate brain. We seek to understand its function and the specific neuronal structures necessary to explain the phenomenology of conscious vision. We describe the relevant ongoing experimental work, focusing in particular on electrophysiological data in the awake macaque monkey. We argue that, at the moment, the most promising empirical approach is to discover the neuronal correlate of consciousness (NCC).

The aim of this chapter is to outline an experimental program for the elucidation of the neuronal basis of consciousness (much of this material is taken from Crick and Koch, 1998). We assume that when people talk about “consciousness,” there is something to be explained. After all, one indubitable fact about the world is that, under certain circumstances, I can “see” or “smell” things, I can remember a friend’s face, and I can imagine a future encounter with her. We assume that the reader has similar experiences, else there would be nothing to explain. We seek to understand the neuronal correlates of this brute fact. We can state bluntly the major question that neuroscience must ultimately answer: It is probable that, at any moment, some active neuronal processes in our heads correlate with consciousness while others do not. What, then, is the difference between them? We refer to the neuronal correlate of consciousness as the NCC. We believe that, at this time, it is empirically most profitable to seek to identify the NCC.

In approaching the problem, we made the tentative assumption (Crick and Koch, 1990) that all the different aspects of consciousness (pain, visual awareness, self-consciousness, and so forth) employ a basic common mechanism, or perhaps a few such mechanisms. We also think precise definitions of consciousness are premature but that any such definition is likely to include attention and some form of short-term memory. We assume that some species of animals—in particular the higher mam-

mals—possess some of the essential features of consciousness, but not necessarily all. It follows that a language system is not essential for consciousness. This is not to say, however, that language does not enrich consciousness considerably.

How can one approach consciousness in a scientific manner? Consciousness takes many forms, but for an initial scientific attack it usually pays to concentrate on the form that appears easiest to study. We chose visual consciousness rather than other forms of consciousness, largely because our visual percepts are especially vivid and rich in information. Furthermore, the visual system of primates appears fairly similar to our own (Tootell et al., 1996), and many experiments on the visual systems have already been done on animals such as the macaque monkey.

Why are we conscious?

We have suggested (Crick and Koch, 1995) that the biological usefulness of visual consciousness in humans is to produce the best current interpretation of the visual scene in the light of past experience, either of ourselves or of our ancestors (embodied in our genes), and to make this interpretation directly available, for a sufficient time, to the parts of the brain that contemplate and plan voluntary motor output, of one sort or another, including speech.

Philosophers have invented a creature called a “zombie,” which is supposed to act just as normal people do but to be completely unconscious (Chalmers, 1995). This seems to us to be an untenable scientific idea, but there is now suggestive evidence that part of the brain does behave like a zombie. That is, in some cases, a person uses the current visual input to produce a relevant motor output, without being able to say what was seen. Milner and Goodale (1995) point out that a frog has at least two independent systems for action. These may well be unconscious. One is used by the frog to snap at small, prey-like objects, and the other for jumping away from large, looming ones. Why does our brain not consist simply of a series of such specialized zombie systems

CHRISTOF KOCH Computation and Neural Systems Program,

FRANCIS CRICK The Salk Institute, La Jolla, Calif.

without any consciousness? Why do we have any conscious mental life at all?

We suggest that such an arrangement is inefficient when very many such systems are required. Better to produce a single but complex representation and make it available for a sufficient time to the parts of the brain that make a choice among many different but possible plans for action. This, in our view, is what “seeing” is about.

Milner and Goodale (1995) suggest that in primates there are two systems, which we have called the on-line and the seeing systems. The latter is conscious, while the former, acting more rapidly, is not. There is anecdotal evidence from sports. It is often stated, for example, that a trained tennis player reacting to a fast serve has no time to see the ball; the seeing comes afterwards. Similarly, a sprinter is believed to start to run before he or she consciously hears the starting pistol.

The nature of the visual representation

We have argued elsewhere (Crick and Koch, 1995) that to be aware of an object or event, the brain has to construct a multilevel, explicit, symbolic interpretation of part of the visual scene. By *multilevel*, we mean, in psychological terms, different levels such as those that correspond, for example, to lines or eyes or faces. In neurological terms, we mean, loosely, the different levels in the visual hierarchy (Felleman and Van Essen, 1991).

The important idea is that the representation should be explicit. We have had some difficulty getting this idea across. By an explicit representation, we mean a smallish group of neurons that employ coarse coding (Ballard, Hinton, and Sejnowski, 1983) to represent some aspect of the visual scene. In the case of a particular face, all of these neurons can fire to somewhat face-like objects (Young and Yamane, 1992). We postulate that one set of such neurons will be all of one type, will probably be fairly close together, and will all project to roughly the same place. If all such groups of neurons (there may be several of them, stacked one above the other) were destroyed, then the person would not see a face, though he or she might be able to see the parts of a face—the eyes, the nose, the mouth, etc. There are other places in the brain that explicitly represent other aspects of a face, such as the emotion the face is expressing or its angle of gaze.

Notice that while the information needed to represent a face is contained in the firing of the ganglion cells in the retina, it lacks an explicit representation for faces.

How many neurons are there likely to be in such a group? This is not yet known, but we would guess that the number to represent one aspect is likely to be closer to 10^2 – 10^3 than to 10^4 – 10^6 .

A representation of an object or an event will usually consist of representations of many of the relevant aspects of it, and these are likely to be distributed, to some degree, over different parts of the visual system. The question of how these are bound together is known as the binding problem (von der Malsburg, 1995).

A great deal of neural activity, most of which is probably unconscious, is usually needed for the brain to construct a representation. It may prove useful to consider this unconscious activity as the computations needed to find the best interpretation, while the interpretation itself may be considered to be the results of the computations, only some of which we are then aware. To judge from our perception, the results probably have something of a winner-take-all character.

As a working hypothesis, we have assumed that only some types of specific neurons will express the NCC. It is already known (see the discussion under “Bistable Percepts”) that the firing of many cortical cells does not correspond to what the animal is currently seeing. An alternative possibility is that the NCC is necessarily global, usually identified with some emergent property of very large and diffuse assemblies of neurons (e.g., Libet, 1993; Popper and Eccles, 1981; Sperry, 1969). In one extreme form this would mean that, at one time or another, any neuron in cortex and associated structures could express the NCC, and it would be foolish to locate consciousness at the level of single neurons. At this point, we feel it more fruitful to explore the simpler hypothesis—that only particular types of neurons express the NCC—before pursuing the more global hypothesis. Such “local” theories of consciousness, which emphasize specific neuronal or cognitive subsystems responsible for the genesis of consciousness, have been less popular (for an earlier perspective broadly compatible with ours, see Schacter, 1989). Note that such locality does not preclude global effects (think of the genes in the nucleus that control properties throughout the cell).

The conscious visual representation is likely to be distributed over more than one area of the cerebral cortex and possibly over certain subcortical structures as well. We have argued (Crick and Koch, 1995) that in primates, contrary to most received opinion, it is not located in primary visual cortex (V1). This is not to say that what goes on in V1 is not important; indeed, it may be crucial for most forms of vivid visual awareness. But we do suggest that the neural activity there is not directly correlated with what is seen.

What is essential for visual consciousness?

The term “visual consciousness” almost certainly covers a variety of processes. When one is actually looking at a

visual scene, the experience is very vivid. In contrast, the visual images produced by trying to remember the same scene are much less vivid and detailed (a vivid recollection is usually called a hallucination). We are concerned here mainly with normal vivid experiences. (It is possible that our visual recollections are dimmer mainly because the back-pathways in the visual hierarchy act on the random activity in the earlier stages of the system.)

Some form of very short-term memory seems almost essential for consciousness, but this memory may be very transient, lasting only a fraction of a second. The existence of iconic memory, as it is called, is well established experimentally (Coltheart, 1983; Gegenfurtner and Sperling, 1993).

Psychophysical evidence for short-term memory (Potter, 1976) suggests that if we do not pay attention to some part or aspect of the visual scene, our memory of it is very transient and can be overwritten (masked) by the following visual stimulus. This probably explains many of our fleeting memories when we drive a car over a familiar route. If we do pay attention (noticing, for example, a child crossing the road), our recollection of this can be longer-lasting.

Our impression that at any moment we see all of a visual scene very clearly and in great detail is illusory. This is due in part to ever-present eye movements and in part to our ability to use the scene itself as a readily available form of memory, since in most circumstances the scene changes rather little over a short span of time (O'Regan, 1992).

Although working memory (Baddeley, 1992) expands the time frame of consciousness, it is not obvious that it is essential for consciousness. It seems to us that working memory is a mechanism for bringing an item, or a small sequence of items, into consciousness. In a similar way, the episodic memory enabled by the hippocampal system (Zola-Morgan and Squire, 1993) is not essential for consciousness, though a person without it is severely handicapped.

Consciousness, then, is enriched by visual attention, though attention may not be essential for visual consciousness to occur (Braun and Julesz, 1998; Rock et al., 1992). Attention is broadly of two types: bottom-up, which is saliency-driven and task-independent; and top-down, which is produced by the planning parts of the brain. Visual attention can be directed either to a location in the visual field or to one or more (moving) objects. The exact neural mechanisms that achieve this are still being debated. Attention is a complicated subject, and we cannot summarize here all the relevant work.

To interpret the visual input, the brain must arrive at a coalition of neurons whose firing represents the best interpretation of the visual scene, often in competition

with other possible but less likely interpretations; and there is evidence that attentional mechanisms bias this competition (Luck et al., 1997).

Recent experimental results

We shall not attempt to describe all the various experimental results of direct relevance to the search for the neuronal correlates of visual consciousness in detail. Rather, we outline a few of them.

ACTION WITHOUT SEEING: CLASSICAL BLINDSIGHT Blindsight occurs in humans when there is extensive damage to cortical area V1 (Weiskrantz, 1997). It has been reproduced in monkeys by complete lesioning of primary visual cortex (Covey and Stoerig, 1995). In a typical case, the patient can indicate, well above chance level, the direction of movement of a spot of light over a certain range of speed, while denying that he sees anything at all. If the movement is less salient, his performance falls to chance; if more salient (that is, brighter or faster), he may report that he had some ill-defined conscious percept ("waving your hand in front of your eyes when they are closed," Weiskrantz, 1997, p. 144), considerably different from the normal one. Other patients can respond to large, simple shapes or colors. While the existence of true blindsight (i.e., the possession of certain residual visual abilities in the absence of any acknowledged awareness) is no longer controversial, its neuronal substrate is (Kentridge, Heywood, and Weiskrantz, 1997; Wessinger, Fendrich, and Gazzaniga, 1997).

The pathways involved have not yet been established. A possible one goes from the superior colliculus to the pulvinar and from there to parts of visual cortex; several other known weak anatomical pathways from the retina and bypassing V1 are also possible. Recent functional magnetic resonance imaging (fMRI) of one blindsight patient, G.Y., directly implicates the superior colliculus as being active—specifically, when G.Y. correctly discriminates the direction of motion of some stimulus without being aware of it at all (Sahraie et al., 1997).

ACTION WITHOUT SEEING: THE ON-LINE SYSTEM The broad properties of the two hypothetical systems—the on-line system and the seeing system—are shown in table 89.1 (following Milner and Goodale, 1995; for a recent review, see Boussaoud, di Pellegrino, and Wise, 1996). The on-line system may have multiple subsystems (for eye movements, for arm movements, for body posture adjustment, and so on). Normally, the two systems work in parallel; indeed, there is evidence that,

TABLE 89.1
*Comparison of the hypothetical on-line system and the seeing system**

	On-Line System	Seeing System
Visual inputs handled	Must be simple	Can be complex
Motor outputs produced	Stereotyped responses	Many possible responses
Minimum time needed for response	Short	Longer
Effect of a few seconds' delay	May not work	Can still work
Coordinates used	Egocentric	Object-centered
Certain perceptual illusions	Not effective	Seen
Conscious	No	Yes

*Based on Milner and Goodale, 1995.

in some circumstances, the seeing system can interfere with the on-line system (Rossetti, 1998).

One striking piece of evidence for an on-line system comes from studies on patient D.F. (Milner et al., 1991). Her brain has diffuse damage produced by carbon monoxide poisoning. She is able to see color and texture very well but is very deficient in seeing orientation and form. In spite of this, she is very good at catching a ball. She can “post” her hand or a card into an elongated slot without difficulty, though she is unable to report the slot’s orientation.

It is obviously important to discover the difference between the on-line system, which is unconscious, and the seeing system, which is conscious. Milner and Goodale (1995) suggest that the on-line system mainly uses the dorsal visual stream. They propose that rather than being the “where” stream, as suggested by Ungerleider and Mishkin (1982), it is really the “how” stream. This might imply that all activity in the dorsal stream is unconscious. They consider the ventral stream, on the other hand, to be largely conscious. An alternative suggestion (Steven Wise, personal communication; and Boussaoud, di Pellegrino, and Wise, 1996) is that direct projections from parietal cortex into premotor areas are unconscious, whereas projections to them via prefrontal cortex are related to consciousness.

We suspect that, while these suggestions about two systems are on the right lines, they are probably oversimplified. The little that is known of the neuroanatomy hints of multiple cortical streams, with numerous anatomical connections between them (Distler et al., 1993). In short, the neuroanatomy does not suggest that the sole pathway goes up to the highest levels of the visual system, and from there to the highest levels of the prefrontal system and then down to the motor output. Rather, there are numerous pathways from intermediate levels of the visual system to intermediate frontal regions (see figure 89.1).

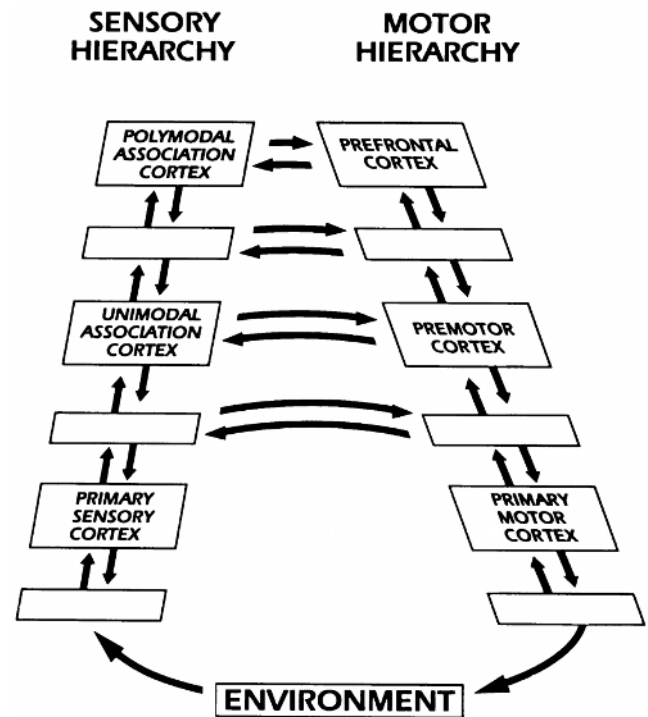

FIGURE 89.1 The fiber connections between cortical regions participating in the perception-action cycle. Empty rectangles stand for intermediate areas or subareas of the labeled regions. Notice that there are connections between the two hierarchies at several levels of the sensory and motor hierarchies, not just at the top level. (From Fuster, 1997; with permission by Lippincott-Raven Publishers.)

We therefore suggest the hypothesis that the brain always tries to use the quickest appropriate pathway for the situation at hand. Exactly how this idea works out in detail remains to be discovered. Perhaps there is competition, and the fastest stream wins. The postulated on-line system would be the quickest of these hypothetical cortical streams. This would be the zombie part of you.

BISTABLE PERCEPTS Perhaps the most important current experimental approach to finding the NCC is the study of the behavior of single neurons—specifically, single neurons in the monkey’s brain when it is looking at something that produces a bistable percept. The visual input, apart from minor eye movements, is constant; but the subject’s percept can take one of two alternative forms. This happens, for example, when one looks at a drawing of the well-known Necker cube.

A more practical alternative is to study binocular rivalry (Myerson, Miezin, and Allman, 1981). If the visual input into each eye is different, but perceptually overlapping, one usually sees the visual input as received by one eye alone, then by the other one, then by the first one, and so on. The input is constant, but the percept changes. Which neurons in the brain mainly follow the input, and which the percept?

This approach has been explored by Logothetis and his colleagues working on the macaque visual system. They trained the monkey to report which of two rivalrous inputs it saw. The fairly similar distribution of switching times strongly suggests that monkeys and humans perceive these bistable visual inputs in the same way. The first set of experiments (Logothetis and Schall, 1989) studied neurons in area MT. The stimuli were vertically drifting horizontal gratings. Of the relevant neurons, only about 35% were somewhat modulated according to the monkey’s reported percept. Surprisingly, half of these responded in the opposite direction to the one expected.

The second set of experiments (Leopold and Logothetis, 1996) used stationary gratings. The orientation was chosen in each case to be optimal for the neuron studied, and orthogonal to it in the other eye. They recorded how the neuron fired during several alterations of the reported percept. While only a small fraction of foveal V1/V2 neurons followed the percept, about 40% of neurons in V4 did. Interestingly, about half of V4 cells were anticorrelated with the stimulus.

The results of the most recent set of experiments (Sheinberg and Logothetis, 1997) are striking (figure 89.2). In this case, the visual inputs include images of humans, monkeys, butterflies, reptiles, and various man-made objects. If a new image is flashed into one eye while the second eye was fixating another pattern, the new stimulus is the one that is always perceived (“flash suppression”). Recordings were made in the upper and lower banks of the superior temporal sulcus (STS) and inferior temporal cortex (IT). Overall, approximately 90% of the recorded neurons in STS and IT reliably predict the perceptual state of the animal. Moreover, many of these neurons respond in a near all-or-nothing fashion, firing strongly for one percept, yet only at noise level for the alternative one.

Bradley, Chang, and Andersen (1998) have studied a different bistable percept in macaque MT using a structure-from-motion paradigm. It is produced by showing the monkey on a TV screen the two-dimensional projection of a transparent, rotating cylinder with random dots “painted” on it, without providing any stereoscopic disparity information. Human subjects exploit structure-from-motion, seeing a three-dimensional cylinder rotating around its axis. But, without further clues, the direction of rotation is ambiguous; observers first report rotation in one direction, then, a few seconds later, rotation in the other direction, and so on. The trained monkey responds as if it saw the same alternation. In their studies on the monkey, about half the relevant MT neurons Bradley and colleagues recorded from followed the percept rather than the “constant” retinal stimulus.

These are all exciting experiments, but they are still in the early stages. Just because a particular neuron follows the percept, it does not automatically imply that its firing is part of the NCC. It is obviously important to discover, for each cortical area, which neurons are following the percept and, most important of all, where they project to. It is, at the moment, technically difficult to do this, but it is essential to have this knowledge, or it will be almost impossible to understand the neural nature of consciousness.

Evicting the NCC from V1

We have argued (Crick and Koch, 1995) that one is not directly conscious of the features represented by the neural activity in primary visual cortex. Activity in V1 may be necessary for vivid and veridical visual consciousness (as is activity in the retina), but we suggest that the firing of none of the neurons in V1 correlates directly with what we consciously see.

Our reasons are that at each stage in the visual hierarchy the explicit aspects of the representation we have postulated is always re-coded. We also assumed that any neurons expressing an aspect of the NCC must project directly, without re-coding, to at least some of the parts of the brain that plan voluntary action—that is what we have argued seeing is for. We think that these plans are made in some parts of frontal cortex.

The neuroanatomy of the macaque monkey shows that V1 cells do not project directly to any part of frontal cortex (Crick and Koch, 1995).

The strategy to verify or falsify this and similar hypotheses is to relate the receptive field properties of individual neurons in V1 or elsewhere to perception in a quantitative manner. Ultimately, this correlation has to be made on an individual trial-to-trial basis. If the structure of perception does not map to the receptive field

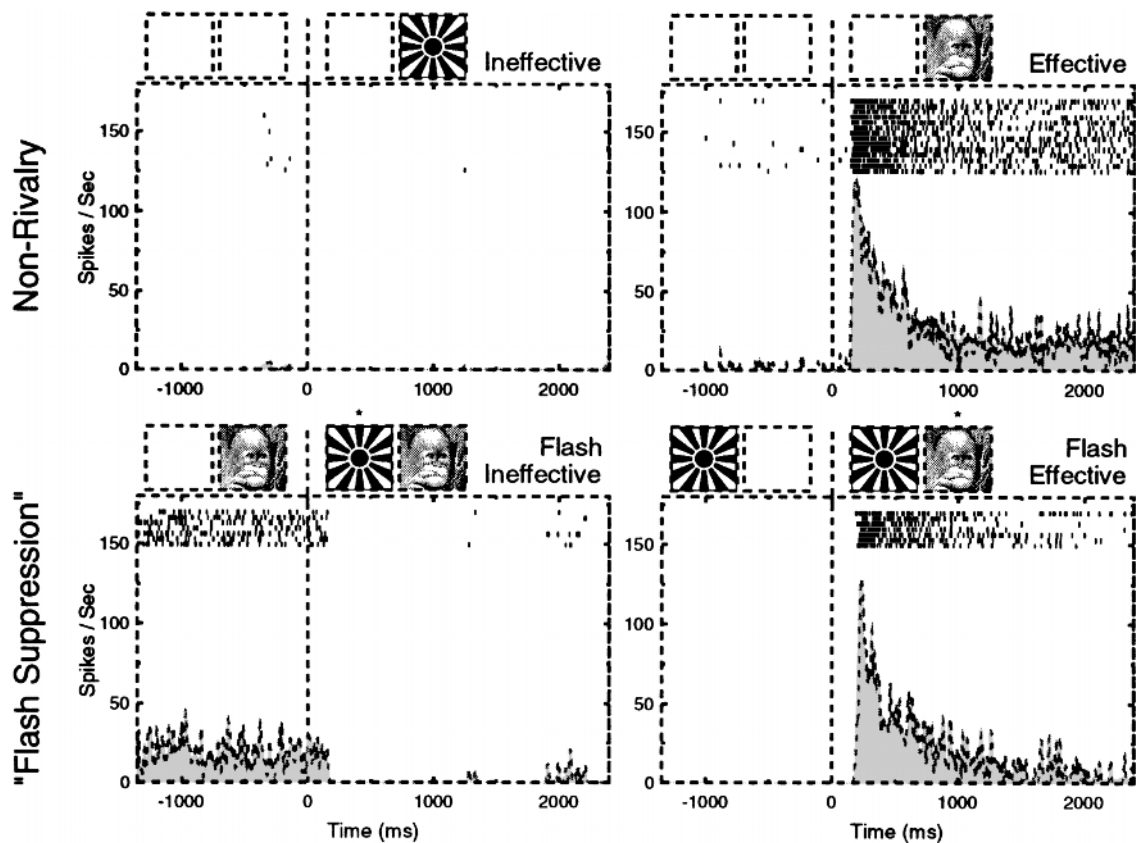

FIGURE 89.2 The activity of a single neuron in the STS of a macaque monkey in response to different stimuli presented to the two eyes. In the upper left panel a sunburst pattern is presented to the right eye without evoking any firing response (ineffective stimulus). The same cell will fire vigorously in response to its effective stimulus—here, the image of an ape’s face (upper right panel). When the monkey is shown the face in one eye for awhile, and the sunburst pattern is flashed onto the monitor for the other eye, the monkey signals that it is “seeing” this new pattern and that the stimulus associated with the rivalrous eye is perceptually suppressed (flash suppression;

lower left panel). At the neuronal level, the cell rapidly shuts down in response to the ineffective yet perceptually dominant stimulus following stimulus onset (at the dotted line) although the cell’s preferred stimulus is still present on the retina. Conversely, if the monkey fixates on the sunburst pattern for a while, and the image of the face is flashed on, it reports perceiving the face, and the cell will now fire strongly (lower right panel). Neurons in V4 are largely unaffected by perceptual changes during flash suppression. (From Sheinberg and Logothetis, 1997)

properties of V1 cells, it is unlikely that these neurons directly give rise to consciousness. In the presence of a correlation between perceptual experience and the receptive field properties of V1 cells, it is unclear whether these cells just correlate with consciousness or directly give rise to it. In that case, further experiments need to be carried out to untangle the exact relationship between neurons and perception.

An example may make this clearer. It is well known that the color we perceive at one particular visual location is influenced by the wavelengths of the light entering the eye from surrounding regions in the visual field (Land and McCann, 1971). It has been shown in the anesthetized monkey (Schein and Desimone, 1990; Zeki, 1983) that neurons in V4, but not in V1, exhibit

this form of partial color constancy, also known as the Land effect. If the same results could be obtained in a behaving monkey, it would follow that it would not be directly aware of the “color” neurons in V1.

In the last several years, a number of psychophysical, physiological, and imaging studies have provided support for our V1 hypothesis, although this evidence falls short of proving it (Cumming and Parker, 1997; He, Smallman, and MacLeod, 1995; Kolb and Braun, 1995; but see Morgan, Mason, and Solomon, 1997). Let us briefly discuss two cases.

When two isoluminant colors are alternated at frequencies beyond 10 Hz, humans perceive only a single fused color with a minimal sensation of brightness flicker. In spite of the perception of color fusion, color opponent

cells in primary visual cortex of two alert macaque monkeys follow high-frequency flicker well above heterochromatic fusion frequencies (Gur and Snodderly, 1997). In other words, neuronal activity in V1 can clearly represent certain retinal stimulation that is not perceived. This is supported by recent fMRI studies on human color perception by Engel, Zhang, and Wandell (1997).

The study by He, Cavanagh, and Intriligator (1996) exploits a common visual aftereffect. If a subject stares for a fraction of a minute at a horizontal grating, and is then tested with a faint grating at the same location to decide whether it is oriented vertically or horizontally, the subject's sensitivity for detecting a horizontal grating will be reduced. This adaptation is orientation-specific—the sensitivity for vertical gratings is almost unchanged—and disappears quickly. He and his colleagues projected a single patch of grating onto a computer screen some 25 degrees from the fixation point. It was clearly visible and their subjects showed the predictable orientation-selective adaptation effect. Adding one or more similar patches of gratings to either side of the original grating removes the lines of the grating from visibility; it is “masked.” Subjectively, one still sees “something” at the location of the original grating, but one is unable to make out its orientation, even when given unlimited viewing time. Yet despite this inability to “see” the adapting stimulus, the aftereffect was as strong and as specific to the orientation of the “invisible” grating as when the grating was visible. What this shows is that visual awareness must occur at a higher stage in the visual hierarchy than orientation-specific adaptation. This aftereffect is thought to be mediated by oriented neurons in V1 and beyond, implying that the NCC must be located past this stage.

Our hypothesis is not disproved by PET experiments showing that V1 can be activated during visual imagery (Kosslyn et al., 1995), though severe damage to V1 is compatible with visual imagery in patients (Goldenberg, Müllbacher, and Nowak, 1995). There is no obvious reason why such top-down effects should not reach V1. This activity would not, by itself, prove that we are directly aware of it, any more than the V1 activity produced there when our eyes are open proves this. We hope that further neuroanatomical work will make our hypothesis plausible for humans. If correct, it would narrow the search to areas of the brain farther removed from the sensory periphery.

The frontal lobe hypothesis

As mentioned several times, we hypothesize that the NCC must have access to explicitly encoded visual information and directly project into the planning stages

of the brain, associated with the frontal lobes in general and with prefrontal cortex in particular (Fuster, 1997). We would therefore predict that patients unfortunate enough to have lost their entire prefrontal cortex on both sides (including Broca's area) would not be visually conscious, although they might still have well-preserved, but unconscious, visual-motor abilities. No such patient is known to us (not even Brickner's famous patient; for an extensive discussion, see Damasio and Anderson, 1993). The visual abilities of any “frontal lobe” patient need to be carefully evaluated using a battery of appropriate psychophysical tests.

The fMRI study of the blindsight patient G.Y. (Sahraie et al., 1997) provides direct evidence for our view by revealing that prefrontal areas 46 and 47 are active when G.Y. is aware of a moving stimulus.

The recent findings of neurons in the inferior prefrontal cortex (IPC) of the macaque that respond selectively to faces—and that receive direct input from regions around STS and the inferior temporal gyrus that are well known to contain face-selective neurons—is very encouraging (Scalaidhe, Wilson, and Goldman-Rakic, 1997; figure 89.3). This raises the question of why face cells would be represented in both IT and IPC. It is unlikely that the same information is represented at two different locations, so it will be important to find out in what way they differ.

Large-scale lesion experiments carried out in the monkey suggest that the absence of frontal lobes leads to complete blindness (Nakamura and Mishkin, 1986; see also Gazzaniga, 1966). One would hope that future monkey experiments reversibly (by cooling and/or injection of GABA agonists) inactivate specific prefrontal areas and demonstrate the specific loss of abilities linked to visual perception while visual-motor behaviors—mediated by the on-line system—remain intact.

It will be important to study the pattern of connections between the highest levels of the visual hierarchy—such as inferotemporal cortex—and premotor and prefrontal cortex. In particular, does the anatomy reveal any feedback loops that might sustain activity between IT and prefrontal neurons? There is suggestive evidence (Webster, Bachevalier, and Ungerleider, 1994) that projections from prefrontal cortex back into IT might terminate in layer 4, but these need to be studied directly.

Some cognitive scientists (in particular Jackendoff, 1987) have argued for an “intermediate-level” theory of consciousness in which neither early sensory processing (the “outer world”) nor high-level three-dimensional information or thoughts (the “inner world”) are directly accessible to consciousness. The intermediate-level hypothesis raises the intriguing possibility that although much of the frontal lobes might be necessary

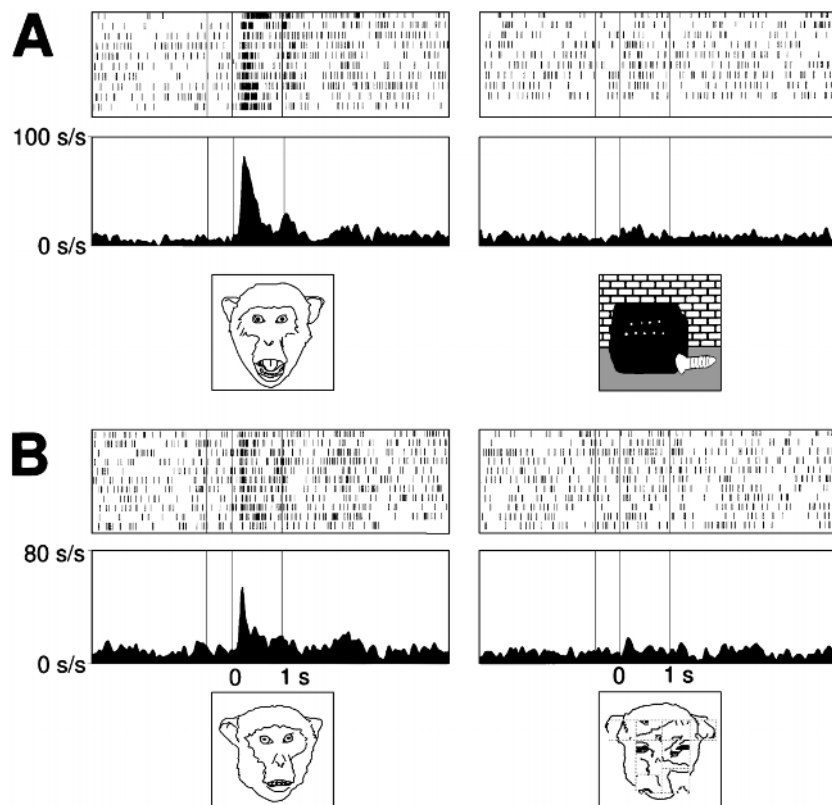

FIGURE 89.3 Face-specific neurons in the inferior prefrontal cortex of the macaque. (A) Firing response of one neuron to its most effective face and nonface stimulus, illustrated by trial rasters and the average spike density function. (B) Response of the same cell to a different face and a scrambled version of this

face. The first vertical line denotes foveal fixation, the second line represents stimulus onset, and the third stimulus offset. Total stimulus duration is 1 s. (From Scaldidhe, Wilson, and Goldman-Rakic, 1997.)

for consciousness, the NCC might be preferentially located in more intermediate levels of cortex, such as the inferior temporal lobes (for a more detailed discussion of this and some experimental ramifications, see Crick and Koch, in press).

Future experiments

At the moment the most promising experiments are those on bistable percepts; these need to be expanded to include other brain areas (in particular prefrontal cortex) in both the monkey and in humans (Lumer, Friston, and Rees, 1998) as well as other percepts. It is important to discover which neurons express the NCC in each case (which neuronal subtype, in what layer, and so on), how they fire (do they fire in bursts), and, especially, to where they project. To assist this, more detailed neuroanatomy of the connectivity will be needed. This is relatively easy to do in the macaque, but difficult in humans (Crick and Jones, 1993). It is also important to discover how the various on-line systems work, so that one can contrast their (unconscious) neuronal activity with the NCC.

It will not be enough to show that certain neurons embody the NCC in certain-limited-visual situations. Rather, we need to locate the NCC for all types of visual inputs, or at least for a sufficiently large and representative sample of them. For example, when one blinks, the eyelids briefly (30–50 ms) cover the eyes, yet the visual percept is scarcely interrupted (blink suppression; Volkman, Riggs, and Moore, 1980). We would therefore expect the NCC to be insensitive to eye-blinks (e.g., the firing activity should not drop noticeably during the blink) but not to blanking out of the visual scene for a similar duration due to artificial means. Another example is the large number of visual illusions. For instance, humans clearly perceive, under appropriate circumstances, a transient motion aftereffect. On the basis of fMRI, it has been found that the human equivalent of cortical area MT is activated by the motion aftereffect (in the absence of any moving stimuli; Tootell et al., 1995). The time course of this illusion parallels the time course of activity as assayed using fMRI. In order to pinpoint the NCC, one would need to identify individual cells expressing this, and similar, visual aftereffects.

In the long run, finding the NCC will not be enough. A complete theory of consciousness is required, including its functional role. With luck, this might illuminate the hard problem of qualia. It is likely that scientists will then stop using the term “consciousness,” except in a very loose way. After all, biologists no longer worry whether a seed or a virus is “alive.” They just want to know how it evolved, how it develops, and what it can do.

The explanation of consciousness is one of the major unsolved problems of modern science. After several thousand years of speculation, it would be very gratifying to find an answer to it.

90 Conscious vs. Unconscious Perception

PHILIP M. MERIKLE AND MEREDYTH DANEMAN

ABSTRACT In this chapter, we discuss three approaches for distinguishing conscious from unconscious perception. The oldest approach uses subjective measures based on people's self-reports regarding whether they are aware of perceiving. A more recent approach uses objective measures based on people's abilities to discriminate between stimulus states such as the presence or absence of a stimulus. Both of these approaches have been used to establish the existence of unconscious perception. With the third approach, the existence of unconscious perception is assumed and the goal is to show that conscious and unconscious perception of the same stimulus information can lead to qualitatively different consequences. The importance of qualitative differences is that they show that unconscious perception is not simply a weak form of conscious perception. We describe how these approaches have been used with neurologically intact individuals and neurological patients to demonstrate unconscious perception and to establish how unconscious perception differs from conscious perception.

Imagine that you are in a lecture hall and the lecturer holds up a series of white flash cards. All you see on each card is a dim, blurred spot, or nothing at all. However, the lecturer tells you that each card contains a single character—either a letter from the set B, Z, K, U, and H or a digit from the set 2, 4, 5, 7, and 9—and she asks you to report the character that you “see” on each card. You comply with her request, even though it feels as if you are guessing. Later, you are surprised to learn that your “guesses” were considerably more accurate than the chance level of performance. This classroom demonstration illustrates one of the earliest approaches to the study of unconscious perception. In fact, Sidis reported a number of similar experiments in 1898. The participants in his experiments also “complained that they could not see anything at all; that even the black, blurred, dim spot often disappeared from their field of vision” and “that they might as well shut their eyes and guess” (Sidis, 1898, p. 171). Despite these complaints, Sidis found that the participants in his studies performed consistently above chance. And on the basis of these findings, he concluded that his experiments indicated “the presence within us of a secondary subwaking self

that perceives things which the primary waking self is unable to get at” (p. 171).

The studies conducted by Sidis illustrate one approach for demonstrating unconscious perception. This approach, which relies on observers' self-reports regarding awareness, is still widely used today, and is one of the two major approaches for demonstrating unconscious perception discussed in this chapter. The other approach for demonstrating unconscious perception discussed in the chapter is an approach that relies on more objective measures of awareness. This alternative approach was developed because some investigators (e.g., Eriksen, 1960) have been reluctant to measure awareness solely on the basis of self-reports, given that so many factors other than awareness can influence self-reports of perceptual experiences. With this second approach, awareness is assessed on the basis of perceptual discriminations, and an inability to discriminate is assumed to indicate an absence of awareness. Although there has been considerable debate regarding the relative merits of subjective measures of awareness based on self-reports and objective measures of awareness based on perceptual discriminations (e.g., Holender, 1986), both approaches have been used successfully to demonstrate unconscious perception. In this chapter, we suggest that both approaches may assess the same underlying subjective awareness of perceiving.

By and large, the goal of the vast majority of studies based on subjective and objective measures of awareness has been simply to demonstrate unconscious perception. A more recent research strategy has been to ask how conscious and unconscious perceptual processes differ in their influence on thoughts, actions, and feelings. This alternative strategy has led to a third approach to the study of unconscious perception—one that emphasizes how unconscious and conscious perception can at times have different consequences. We describe examples of studies in which qualitative differences have been established, and we suggest that studies of qualitative differences provide stronger evidence both for unconscious perception per se and for the importance of the distinction between conscious and unconscious perception than is provided by any approach that simply attempts to demonstrate unconscious perception.

Demonstrations of unconscious perception

SUBJECTIVE MEASURES OF AWARENESS One of the most reliable ways to demonstrate perception without awareness is simply to ask people whether or not they are aware of perceiving. If awareness is reported, conscious perception is assumed, whereas if no awareness is reported and perception can be demonstrated, unconscious perception is assumed. In the following sections, we review how self-reports have been used successfully to demonstrate perception in the absence of an awareness of perceiving. We first consider studies in which stimuli have been presented below a subjective threshold for awareness to neurologically intact individuals, then we consider studies in which stimuli have been presented to neurological patients who have no awareness of perceiving.

Subjective thresholds In studies based on subjective thresholds, the basic strategy is to systematically degrade the stimulus conditions until the quality of the stimulus information is so poor that observers claim not to be able to perceive the stimuli. The subjective threshold for awareness is defined in terms of the minimal stimulus conditions necessary for someone to experience the awareness of perceiving (cf. Cheesman and Merikle, 1986), and the primary question addressed by these studies is whether stimuli presented below the subjective threshold are nevertheless perceived.

Some of the best examples of studies based on subjective thresholds come from the earliest studies of unconscious perception. The studies conducted by Sidis (1898) are good examples of this general approach. Another example is a study conducted by Dunlap (1900) showing that the Müller-Lyer illusion can be induced by “stimulation of such low intensity as to be imperceptible” (p. 435). Examples of the stimuli used by Dunlap are shown in figure 90.1. The task for the participants was simply to indicate which line segment appeared to be longer. For line A, both the left and right segments are equal in length; and, not surprisingly, the participants showed no bias in judging either the left or right segment as being longer. However, when Dunlap added the faint angular lines shown in

FIGURE 90.1 Examples of the stimuli used by Dunlap (1900).

line B, the participants were more likely to indicate that the left segment was longer than the right segment. Given that the angular lines were presented at an intensity below the level of conscious perception, Dunlap concluded that “we have evidence for the belief that under certain conditions things of which we are not . . . conscious have their immediate effects on consciousness” (p. 436).

Over the years, there have been countless studies demonstrating perception of information presented below a subjective threshold for awareness. Many of these studies were conducted during the late 1800s and early 1900s when consciousness was a central topic in psychology. These studies showed that the following types of information can be perceived without awareness: (1) visual characters such as letters or digits (e.g., Sidis, 1898); (2) names of letters whispered so faintly that “no sound whatever could be heard” (e.g., Stroh, Shaw, and Washburn, 1908); (3) small differences in the weight of two objects (e.g., Peirce and Jastrow, 1884); (4) geometric figures such as circles, triangles, and squares (e.g., Williams, 1938); and (5) orientations of lines as vertical, horizontal, or diagonal (e.g., Baker, 1937). In more recent studies, it has been shown that the meaning of words can be perceived under conditions that do not lead to the subjective experience of perceiving (e.g., Cheesman and Merikle, 1986; Debner and Jacoby, 1994; Merikle, Joordens, and Stolz, 1995) and that attention can be directed to locations in the visual field by visual cues presented below the subjective threshold for awareness (McCormick, 1997). In addition, in a recent study of the perception of the emotions expressed in pictures of human faces, fMRI has revealed that fearful and happy faces lead to differential activation in the amygdala even when the pictures are presented under conditions that make it impossible for participants to explicitly identify the emotion expressed in the faces (Whalen et al., 1998). Taken together, the results of both the older studies and the more recent studies show that a considerable amount of information is perceived even when observers do not report any awareness of perceiving.

Neurological patients A striking characteristic of a number of neurological syndromes is that even though patients may claim that they do not see particular stimuli, they can nevertheless respond on the basis of information conveyed by the very same stimuli that they claim not to see (cf. Schacter, McAndrews, and Moscovitch, 1988). Such dissociations between patients’ self-reports and their performance define a number of neurological syndromes. Perhaps the best known example is the blindsight demonstrated when patients with dam-

age to the primary visual cortex report no awareness of objects but correctly guess the size, shape, or orientation of objects presented within the “blind” area of the visual field (e.g., Weiskrantz, 1986). Other examples of perception in the absence of the subjective experience of perceiving are found in studies of prosopagnosia or face agnosia (cf. Young, 1994). Although prosopagnosics may consciously experience looking at a person’s face in the sense that they report “I see a face,” they are unable to identify the person even though the person may be well known to them. Thus, based on their self-reports, prosopagnosics have no awareness of perceiving any information regarding whose face they may be viewing. However, despite this inability to consciously identify faces, some prosopagnosics are able to choose which of two names goes with the face that they claim not to be able to identify (e.g., De Haan, Young, and Newcombe, 1991; Sergent and Poncet, 1990). Thus, despite their claims to the contrary, prosopagnosics are able to perceive faces, albeit unconsciously.

Visual neglect is another syndrome that provides evidence regarding the types of information that may be perceived despite patients’ claims to the contrary. Patients with visual neglect claim not to see stimuli presented to the side of a visual display that is contralateral to their lesion. One way in which this deficit manifests itself is in situations in which stimuli are presented simultaneously to the left and right visual fields. For example, if patients with lesions in the parietal lobe of the right hemisphere are shown a picture of an apple to the left of fixation and a picture of a comb to the right of fixation, most patients will be able to name the comb, but few if any patients will be able to name the apple. But despite this absence of awareness of stimuli presented to the neglected visual field, patients with visual neglect perceive sufficient information to make accurate judgments regarding whether a word or picture presented to the neglected visual field is the same as or different from the consciously perceived word or picture presented to the normal visual field (Volpe, LeDoux, and Gazzaniga, 1979).

Stimuli presented to the neglected visual field can also influence a patient’s reactions to the consciously perceived stimuli presented to the normal visual field. For example, Berti and Rizzolatti (1992) presented a picture of an animal (e.g., bird, rat) or a fruit (e.g., apple, pear) to the normal visual field, and the patients’ task was to categorize each target picture as being either an animal or a fruit. Each target picture was preceded by one of three types of pictures presented to the neglected visual field. In the highly congruent condition, the picture presented to the neglected field (e.g., a duck) was identical to the target picture. In the congruent condi-

tion, the picture presented to the neglected field (e.g., a rat) was a different example from the same category as the target picture (e.g., a duck). In the noncongruent condition, the picture presented to the neglected field (e.g., a duck) was a picture from the other category (e.g., grapes). Berti and Rizzolatti found that the time taken to categorize a target was faster in both the highly congruent and congruent conditions relative to the noncongruent condition. These findings demonstrate that the neglect patients perceived the meaning of the pictures presented to the neglected visual field despite their inability to name the pictures.

These dissociations between the ability of patients to explicitly identify or name stimuli and their performance on tasks such as same/different judgments or semantic categorization are similar to the dissociations found when information is presented below the subjective threshold for awareness to neurologically intact individuals. Thus, the results from studies with neurological patients lead to a similar conclusion: Considerable information is perceived even when self-reports indicate an absence of an awareness of perceiving.

OBJECTIVE MEASURES OF AWARENESS In 1960, Eriksen suggested that the ability of observers to discriminate between alternative stimulus states is a better measure to distinguish conscious from unconscious perception than are observers’ self-reports of awareness. This suggestion followed from Eriksen’s concern that self-reports can be influenced by many factors other than a person’s subjective awareness. It is always possible that statements indicating an absence of an awareness of perceiving simply reflect a person’s preconceived ideas concerning the value of particular types of perceptual experiences for making decisions rather than a true absence of conscious perception (cf. Merikle, 1984). For this reason, Eriksen suggested that the distinction between conscious and unconscious perception is best defined in terms of an observer’s ability to discriminate between alternative stimulus states. Thus, an inability to discriminate between two stimulus states, such as the presence or absence of a stimulus, indicates a complete absence of awareness of the perceptual characteristic(s) that distinguish one stimulus state from the other. Conversely, if it is possible to discriminate one stimulus state from another, then this indicates that the stimuli are consciously perceived. Eriksen’s suggestion led to the idea that awareness should be defined objectively in terms of discriminative responding rather than subjectively in terms of self-reports of awareness.

Objective thresholds Perception below an objective threshold for awareness was first demonstrated by

Marcel (1974/1983). In a series of studies, he showed that semantic priming was produced by words presented under such poor stimulus conditions that observers could not tell when a word was present or absent. Marcel based his experiments on the well known finding that the time to respond to a target word is facilitated (i.e., primed) when it is preceded by a semantically related word (e.g., Meyer and Schvaneveldt, 1976). For example, the letter string *doctor* can be classified as a word faster when it follows the word *nurse* than when it follows the word *bread*. Marcel's important new variation was that he presented the words that served as primes under two different conditions. In one condition, the primes were clearly visible; in the other, the primes were so degraded by a visual mask that observers could not detect whether or not a prime had been presented. Marcel found that the magnitude of semantic priming was similar in the two conditions. In other words, the undetectable primes were as effective as the clearly visible primes. On the basis of these findings, Marcel concluded that the meaning of words can be perceived even under conditions in which there is no awareness of perceiving the words.

Marcel's basic methodology for demonstrating semantic priming without awareness has now been repeated in many different experiments. Many studies have demonstrated that unconsciously perceived words can prime decisions regarding consciously perceived words (e.g., Balota, 1983; Dagenbach, Carr, and Wihelmsen, 1989; Fowler et al., 1981; Groeger, 1984). Moreover, other studies have demonstrated that unconsciously perceived pictures (e.g., McCauley et al., 1980) and unconsciously perceived auditory stimuli (Groeger, 1988) can prime decisions regarding subsequently presented target words. In addition, there is evidence that the affective valence of unconsciously perceived words (e.g., love, grief) can prime evaluative decisions (i.e., good vs. bad) of target words (Greenwald, Klinger, and Liu, 1989), and that the emotion expressed in unconsciously perceived faces (e.g., happiness vs. anger) can influence subsequent evaluative judgments of unfamiliar Chinese ideographs (Murphy and Zajonc, 1993). Assuming that objective thresholds for awareness were successfully established in these studies, the combined results provide compelling evidence that stimuli are perceived even when it is not possible to discriminate between alternative stimulus states.

Neurological patients Given the success of experiments with neurologically intact individuals in demonstrating perception in the absence of discrimination, similar experiments have been conducted with prosopagnosics and patients with visual neglect. In general, the results of these studies with neurological patients lead to the same

conclusion as the studies with neurologically intact individuals. They show that stimulus information is perceived even when the patients are unable to make overt discriminations between alternative stimulus states.

Bauer (1984) reported one of the first studies in which awareness was assessed by an objective measure of a patient's ability to discriminate between alternative stimulus states. In his study, a patient with prosopagnosia was shown two sets of photographs of faces. One set consisted of ten well-known people (e.g., actors, athletes) and the other set consisted of eight family members. While viewing each face in each set, the patient heard five spoken names, one of which corresponded to the face. The patient was asked to select the name that went with each face. Not surprisingly, the number of correct responses did not differ from chance, indicating that the patient was unaware of whose face he was viewing. But though the patient was unable to overtly recognize the correct names, his galvanic skin response (GSR) indicated that he was able to unconsciously recognize the names that corresponded with the faces. Bauer measured the patient's GSR to each of the names presented with each face, and found that the correct names elicited the largest change in GSR more often than would be expected on the basis of chance. The fact that the correct names elicited large GSRs even though the patient could not select the correct names provides strong evidence that faces can be unconsciously perceived by prosopagnosics (see also Tranel and Damasio, 1988).

Objective measures of discriminative responding have also been used with both prosopagnosic patients and patients with visual neglect to demonstrate that stimuli that cannot be discriminated can nevertheless prime decisions regarding targets. For example, Young and De Haan (1988) have found that a prosopagnosic patient, PH, is not able to discriminate familiar from unfamiliar faces. Nevertheless, PH can classify a printed name (e.g., *Prince Charles*) as being familiar more quickly when it follows the face of a related person (e.g., Princess Diana) than when it follows the face of an unrelated person (e.g., Nancy Reagan) (Young, Hellawell, and De Haan, 1988). Primes that cannot be discriminated have also been shown to facilitate neglect patients' subsequent decisions regarding targets (e.g., Ladavas, Paladini, and Cubelli, 1993; McGlinchey-Berroth et al., 1993; 1996). Consider, for example, the study reported by McGlinchey-Berroth and colleagues (1993). They compared the magnitude of priming produced by pictures presented to the neglected field or the normal field, measuring the speed with which patients were able to decide whether a centrally presented letter string was a word or nonword. They presented a picture (e.g., cup, hat) to one visual field immediately before a target word (e.g., *saucer*) or nonword

(e.g., *spiger*) was presented. On some trials, the prime and target were semantically related (e.g., a picture of a cup followed by the word *saucer*), whereas on other trials the prime and target were unrelated (e.g., a picture of a pig followed by the word *saucer*). They found equivalent priming for pictures presented to either visual field, even though, as established in a separate experiment, the neglect patients could not make correct forced-choice decisions regarding the pictures presented to the neglected field. Similar results have been found when the primes are words rather than pictures (McGlinchey-Berroth et al., 1996). Taken together, the results of the studies with the prosopagnosic patient PH and the studies with neglect patients show that these patients perceive the meaning of stimuli even when they are unable to make correct forced-choice discriminations between the alternative stimuli.

SUBJECTIVE VS. OBJECTIVE MEASURES OF AWARENESS

Studies based on subjective and objective measures assess awareness in very different ways. But despite these methodological differences, the results of studies based on both types of measures lead to similar conclusions. How can such apparently different measures of awareness lead to such similar conclusions? There are two possible answers to this question.

One answer is that objective measures of awareness are often influenced by subjective factors, such as a person's beliefs regarding the quality of the perceived information. For example, if someone is asked to discriminate between two stimulus states, such as the presence or absence of a stimulus, and there is no subjective awareness of perceiving, there is often a bias to say "absent" or "no stimulus" each time a decision is requested (cf. Merikle, 1982). More generally, when someone is asked to discriminate between alternative stimulus states and there is no subjective awareness of perceiving, there may be no motivation to perform the task. An unmotivated observer may show a bias to choose one of the response alternatives or a bias to choose a response alternative in an unsystematic manner each time a response is requested. In either case, the observed performance will simply reflect the observer's belief that no useful information was perceived; hence an objective measure of awareness will reveal nothing more than that which could be assessed by self-reports of awareness.

A second answer to the question is that objective measures of awareness are often based on so few trials that relatively high levels of discriminative responding do not differ statistically from the chance level of performance (cf. Macmillan, 1986; Merikle, 1982). Suppose, for example, an objective measure is based on a presence vs. absence discrimination and there is a total of 50

trials (25 present trials and 25 absent trials). Then the confidence interval ($p < .05$) around the chance level of performance (50% correct) ranges from 38% to 62% correct. With such a large confidence interval, one may conclude, incorrectly, that discriminative responding does not differ from chance. But if discriminative responding is actually above chance, the results may simply show that information is perceived under conditions in which perception is not accompanied by the subjective awareness of perceiving.

Despite the obvious methodological differences that distinguish objective and subjective measures, it is now clear that in many contexts objective and subjective measures assess the same underlying subjective awareness of perceiving. Furthermore, objective measures often do not provide any information that cannot be gained from the more straightforward approach of simply asking observers to report the presence or absence of awareness. In reaction to this state of affairs, some investigators have tried to find better objective measures that can then be used to show that perception does in fact occur below an objective threshold for awareness (e.g., Draine and Greenwald, 1998; Greenwald, Draine, and Abrams, 1996; Snodgrass, Shevrin, and Kopka, 1993). This approach can be successful for demonstrating unconscious perception; but unless it is possible to find objective measures that assess conscious perception *exclusively*, such an approach will inevitably underestimate the influence of unconsciously perceived information on thoughts and actions (cf. Merikle and Reingold, 1998). All measures of perception can, in principle, be influenced by both consciously and unconsciously perceived information. Hence any set of experimental conditions that leads to lower performance on an objective measure of perception will reduce not only the influence of consciously perceived information but the influence of unconsciously perceived information as well. The only alternative to finding better objective measures of awareness is to develop better ways to use self-reports of awareness. Notwithstanding a justified uneasiness about using self-reports as the sole basis for distinguishing conscious from unconscious perception, all things considered, self-reports of awareness offer both a direct and accurate indication of the presence or absence of the subjective awareness of perceiving in many contexts (cf. Chalmers, 1996; Merikle, 1992).

Qualitative differences between conscious and unconscious perception

The importance of the distinction between conscious and unconscious perception is sometimes overlooked. Surely, the distinction is much more significant and interesting if

the consequences of conscious and unconscious perception are qualitatively different, so that unconscious perception is not simply a weak form of conscious perception (cf. Dixon, 1971; Merikle, 1992; Shevrin and Dickman, 1980). It has even been suggested that the distinction between conscious and unconscious perception would be of limited value if conscious and unconscious perception did *not* lead to different consequences (e.g., Reingold and Merikle, 1990). For this reason, it is important to assess the ways in which conscious perception differs from unconscious perception.

In the following sections we describe studies that show a qualitative difference in the influence of consciously and unconsciously perceived stimuli. These studies were based on subjective measures of awareness. The general research strategy in these studies was to use self-reports to establish the conditions under which perception is either accompanied or unaccompanied by the subjective awareness of perceiving, and then to show that information perceived under these two conditions leads to qualitatively different consequences. Although this research strategy has most often been used in studies with neurologically intact individuals, it has also been used in studies with neurological patients.

NEUROLOGICALLY INTACT INDIVIDUALS It is often assumed that conscious perception enables one to use perceived information to act on the world and to produce effects on the world (cf. Chalmers, 1996; Searle, 1992), whereas unconsciously perceived information leads to more automatic reactions that cannot be controlled by the perceiver. This distinction between the controlled use of consciously perceived information and the more automatic influences of unconsciously perceived information has been captured in a number of studies.

One example of this type of experiment is a study reported by Debner and Jacoby (1994). In their study, a single word was presented and masked on each trial. The interval between the onset of the word and the onset of the mask was either relatively short (e.g., 50 ms), so that most of the words were unconsciously perceived, or somewhat longer (e.g., 150 ms), so that most of the words were consciously perceived. Immediately following the mask, the first three letters of the word were presented once again. At this point, the participants were told to complete the word stem with any word that came to mind except the word that had just been presented. Thus, if the word presented on a trial was *dough*, the letter-stem *dou* was presented immediately thereafter, and the participants were instructed to use any word except *dough* to complete the word stem. For example, the participants could complete the word stem with *doubt* or *double* but not *dough*. Debner and Jacoby (1994) found that the par-

ticipants had difficulty following the instructions when the words that preceded the word stems were unconsciously perceived because of the short (50-ms) duration. Despite explicit instructions to the contrary, the participants used these words to complete the word stems. This failure to exclude unconsciously perceived words was not due to some perverse desire on the part of the participants not to cooperate: When the words were presented for the slightly longer duration (150 ms), the participants successfully excluded the words that were presented immediately before the word stems. These results are completely consistent with the idea that unconsciously perceived information leads to automatic reactions that cannot be controlled by a perceiver. In contrast, consciously perceived information allows individuals to use this information to guide their actions so that they are able to follow the instructions.

Another example of how unconscious perception leads to automatic reactions and conscious perception allows individuals to modify their reactions comes from a series of experiments showing that prediction based on stimulus redundancy occurs only when the predictive stimuli are consciously perceived (e.g., Merikle and Joordens, 1997). These experiments were based on a two-color variant of the Stroop (1935) color-word interference task. On each experimental trial, either the word *RED* or the word *GREEN* was presented so that it was either consciously or unconsciously perceived. A patch of color that was also either red or green was then shown. The task for the participants was simply to name the color of each color patch as fast as possible. The standard result found with this task is that it takes more time to name a color patch (e.g., green) when it follows an incongruent color word (e.g., *RED*) than when it follows a congruent color word (e.g., *GREEN*). Presumably, this occurs because participants are unable to avoid reading the word even though they are not required to read it, and reading a color word that represents a conflicting color concept (e.g., *RED*) interferes with naming the color patch (e.g., green). In the Merikle and Joordens experiments, this standard interference effect in color naming was found independent of whether the preceding words were consciously or unconsciously perceived. However, when the experimental conditions were changed so that 75% of the word/color-patch pairings were incongruent (i.e., *GREEN*/red or *RED*/green) and the remaining 25% of the word/color-patch pairings were congruent (i.e., *GREEN*/green or *RED*/red), the results depended on whether the words were consciously or unconsciously perceived. When the words were consciously perceived, it actually took *LESS* time to name a color patch when it followed an incongruent color word (e.g., *GREEN*/red) than when it followed a

congruent color word (e.g., *GREEN*/green). What seems to have happened is that the participants capitalized on the predictive information provided by the words; they learned to expect that the color patch on each trial would be the color NOT named by the preceding word. This predictive strategy facilitated performance on the incongruent trials and slowed performance on the congruent trials, leading to a reversal of the standard result. In contrast, when the words were unconsciously perceived, the standard Stroop interference effect was found independent of the predictive relation between the words and color patches. In other words, the participants did not make use of the predictive information provided by the words to change their expectations. These results provide another demonstration of how unconscious perception leads to automatic reactions, whereas conscious perception allows individuals to use the perceived information to guide their actions so that they can react to stimuli in a more flexible manner.

NEUROLOGICAL PATIENTS In general, there has been little emphasis on showing qualitative differences in the consequences of information perceived with and without awareness in neurological patients. However, there is at least one interesting example of the success of this approach in studies of one patient with visual form agnosia (Milner and Goodale, 1995). The patient, DF, has bilateral damage to the lateral occipital cortex and is not able to give an accurate report of the location of objects in space; nor is she able to describe other characteristics of objects such as their shape, size, or orientation. In fact, based on both her self-reports and her inability to discriminate between different objects, DF does not appear to have any awareness of perceiving objects in space. But despite what is clearly an absence of relevant conscious perceptual experiences, DF is able to reach successfully and pick up objects. In addition, when DF reaches for objects, she shapes her hand so that her grip is adjusted to accommodate different-sized objects even though her self-reports indicate that she has no awareness of how the objects may differ in size. These dissociations between DF's conscious perceptual experiences and her skilled actions directed toward objects have led Milner and Goodale to suggest that there are two quite separate visual pathways: the ventral stream which mediates conscious perception of objects, and the dorsal stream which mediates the guidance of skilled actions directed toward objects independent of whether or not the objects are consciously perceived.

The idea that the conscious perception of objects and the visuomotor control of reaching for objects are mediated by separate visual pathways gains strong sup-

port from studies of qualitative differences in reaching between DF and neurologically intact individuals. Goodale, Jakobson, and Keillor (1994) conducted a series of studies in which neurologically intact individuals and DF were either required to reach for a target object while the object was in view or to pantomime reaching for the object two seconds after viewing it. Not surprisingly, introducing a delay between viewing the object and reaching for it led to a number of differences in the reaching movements of both the neurologically intact individuals and DF. However, there was an important difference in the way normal individuals and DF scaled their grips to accommodate different-sized objects when there was a delay between viewing an object and reaching for it. For neurologically intact individuals, increases in object width led to corresponding increases in the maximum grip aperture exhibited when they mimed reaching for the objects. In contrast, when DF mimed reaching for different-sized objects following a delay, she did not scale her grip. Rather, her maximum grip aperture was basically the same irrespective of the actual size of the object.

These findings demonstrate a rather dramatic difference between the consequences of conscious and unconscious perception. When objects are in view and reaching is immediate, both DF and neurologically intact individuals can direct actions toward the objects on the basis of the unconsciously perceived information provided by the dorsal visual pathway which mediates the visuomotor control of reaching when objects are in view. However, the visuomotor systems operate in real time using current visual information. Thus, in order to mediate a temporal interval between viewing an object and reaching for the object, it is necessary to form a representation of the object based on different information than is provided by the dorsal pathway. Milner and Goodale (1995) suggest that the ventral pathway provides the information that allows neurologically intact individuals to form conscious perceptual representations of objects. These conscious representations can then be used to guide visuomotor actions, such as scaling grip size to object size, following a temporal delay between viewing and reaching. In contrast, DF is unable to form conscious representations of objects that provide sufficient information to guide her visuomotor actions. As a consequence, when she reaches for an object following a delay, she does not scale her grip to the size of the object.

Concluding comments

The question of whether unconscious perceptual processes play an important role in determining conscious

experiences, feelings, thoughts, and actions has dominated much of the research on consciousness during the past 100 years. One reason for the fixation on this particular question is our intellectual heritage. Descartes' famous dictum "I think therefore I am" led to the belief that consciousness and mind are one and the same (cf. Rorty, 1979). Given this belief, any evidence for unconscious perception attracts attention because it challenges the conventional view of mind. Another reason that so much effort has been directed toward demonstrating the existence of unconscious mental processes is that our conscious experiences give us the illusion that all important mental processes are conscious. Our feelings, thoughts, and actions almost always occur in temporal contiguity with ongoing conscious experiences. This leads us to attribute our feelings, thoughts, and actions to these ongoing conscious experiences. Taken together, both our intellectual heritage suggesting that mind and consciousness are synonymous and our delusion that conscious mental processes are the only important mental processes probably account for the continual interest in and fascination with demonstrations of unconscious perception in both neurologically intact individuals and neurological patients. It also probably accounts for why so much effort has been devoted to demonstrating the existence of unconscious processes.

Given the evidence that has been amassed during the past 100 years, there is now little doubt that unconscious processes play an important role in determining feelings, thoughts, and actions. For this reason, research regarding conscious and unconscious perception is now beginning to focus on the differences that distinguish conscious from unconscious perception. Not only do the qualitative differences that have been established show how conscious and unconscious perception differ, but they also provide further confirmation of the importance of distinguishing between conscious and unconscious perceptual processes. Qualitative differences show that unconscious perception is not simply a weak form of conscious perception and that conscious perception and unconscious perception of the same stimuli can at times lead to qualitatively different consequences.

Now that the distinction between conscious and unconscious perception has been shown to have a firm empirical basis, future experimental studies can continue to explore the characteristics that distinguish conscious from unconscious perception. It will be important to determine exactly what types of information can and cannot be perceived unconsciously, what types of information may be more readily perceived unconsciously than consciously, what the duration of the impact of unconsciously perceived information may be, and whether some individuals are particularly sensitive to un-

conscious influences and conversely whether some individuals are particularly insensitive to unconscious influences. With the available tools, it should be possible to begin to tease apart the factors determining how different individuals and different contexts lead to different reactions to both consciously and unconsciously perceived information.

ACKNOWLEDGMENTS Preparation of this chapter was facilitated by grants from the Natural Sciences and Engineering Research Council of Canada.

91 The Neural Correlates of Consciousness: An Analysis of Cognitive Skill Learning

MARCUS E. RAICHLE

ABSTRACT This chapter presents a functional brain imaging strategy using positron emission tomography (PET) and functional magnetic resonance imaging (fMRI) to isolate neural correlates of consciousness in humans. This strategy is based on skill learning. In the example presented (rapidly generating verbs for visually presented nouns), a cognitive skill is examined before and after practice. As shown, there are marked qualitative differences in the neural circuitry supporting performance of this task before and after practice. These include both increases and decreases from a baseline level of activity in the brain. An important concept considered in this chapter is that of a baseline level of brain activity in conscious humans.

Two components of our conscious behavior are *content* and *arousal* (Plum and Posner, 1980). One of the great challenges of modern neurobiology is to identify the brain systems responsible for these components. As Damasio (1995) has stated, “[K]nowing *how* [the brain engenders consciousness], to a considerable extent, requires that we first know *where*.”

Much work points to systems ascending from the reticular core of the brainstem via the thalamus to the cortex as responsible for arousal or alert wakefulness (Steriade, 1996a,b). We are much less certain, once alert wakefulness has been achieved, which cortical systems are responsible for the content of our consciousness. One of the difficulties in identifying these cortical systems is distinguishing them from those concerned with the many nonconscious cognitive, attentional, and emotional processes that occur in support of our conscious experiences. Several approaches have been used.

One approach is to examine patients with lesions that deprive them of some aspect of their normal conscious experience. Typical of such an approach is the study of patients with blindsight (Weiskrantz, 1986, 1997). Such patients, fully awake and otherwise alert, have lost the conscious perception of visual information presented to their blind hemifield. However, information entering the blind hemifield still influences behavior. The inference to be drawn is that the area of the brain damaged

by the lesion contributes to the content of conscious experience.

A second approach is to examine normal activities in which consciousness is transiently suspended. Francis Crick and Christof Koch (1998) have provided a recent review of this approach. A typical experiment might involve an analysis of the suppression of conscious visual experience during eye movements, or so-called saccadic suppression (Bridgeman, Hixson, and Velichovsky, 1994). During saccadic suppression, visual perception is suspended, yet information presented during this period of time influences behavior. By identifying changes in the neural circuitry that occur when a conscious visual perception is momentarily suspended one would hope to identify regions that contribute to conscious experience. Functional brain imaging with positron emission tomography (PET) has been used to identify changes during saccadic suppression in humans (Paus et al., 1995).

According to William James, “Habit diminishes the conscious attention with which our acts are performed” (James, 1890). This comment captures the essence of a third approach. In some ways analogous to the second, this approach involves identifying the brain systems supporting a task when it is novel and effortful then comparing these systems to those engaged when the task is routine and reflexive. The performance demands of such a task must necessarily be sufficient to require conscious attention (or “willed action”; see Frith et al., 1991) for its initial performance. The brain systems unique to the novel state, if identified by comparison with the practiced state, then become candidate systems necessary for conscious experience.

Because tasks involving motor as well as cognitive skills can be transformed from reflective, effortful tasks to reflexive, seemingly effortless tasks within a short period of time (Petersen et al., 1998), it is feasible to employ this third approach with modern functional imaging techniques. We already know from such functional imaging studies in normal humans that this transformation is accompanied by dramatic changes in the underlying brain circuitry concerned with the task (Raichle et al., 1994a). These transformations provide important insights into

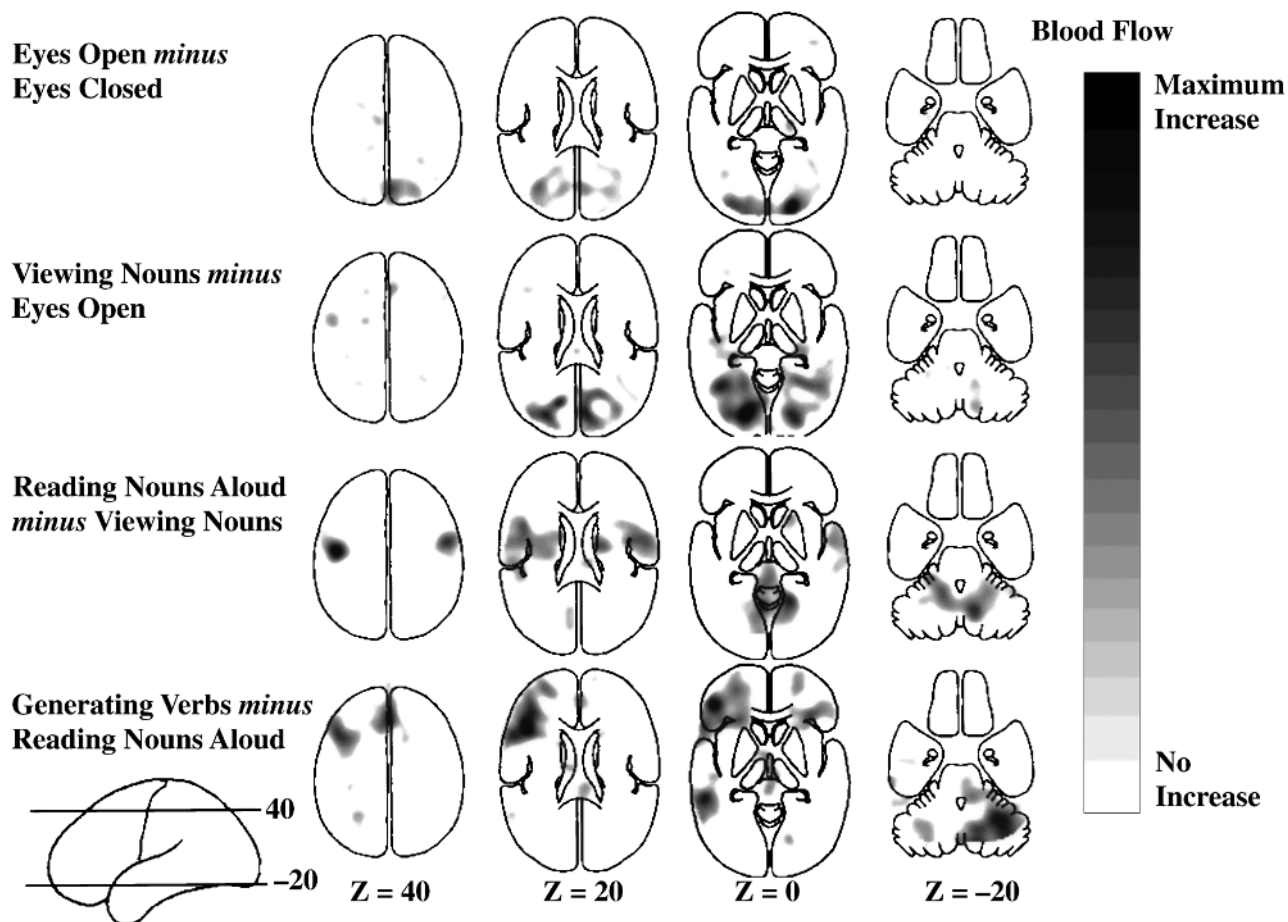

FIGURE 91.1 Four different hierarchically organized conditions are represented in these mean blood flow difference images obtained with PET. All of the changes shown in these images represent *increases* over the control state for each task. A group of normal subjects performed these tasks involving com-

mon English nouns (Petersen et al., 1988, 1989; Raichle et al., 1994b). These horizontal images are oriented with the front of the brain on top and the left side to the reader's left. Z = 40 indicates millimeters above and below a horizontal plane (Z = 0) through the brain (Fox, Perlmuter, and Raichle, 1985).

those brain systems concerned with conscious elements of naïve task performance.

It is the purpose of this chapter to explore the use of this approach in the context of a simple word reading paradigm involving cognitive skill learning in normal human subjects. As will become apparent, the results present a complex picture of widely distributed change (both increases and decreases) in the activity of brain systems uniquely associated with naïve task performance. The richness of the information provided should stimulate, as well as constrain, theories about brain systems serving consciousness.

The paradigm

Studies of word reading have played a central role in functional brain imaging studies of language over the past decade (for recent reviews see Fiez and Petersen, 1998; Posner and Pavese, 1998). This work has benefited from

the large amount of information already known about this skill (for review see Rayner and Pollatsek, 1989). These extant behavioral data on word reading have provided the basis for the design of many imaging experiments with both positron emission tomography (PET) and functional magnetic resonance imaging (fMRI).

Beginning in the 1980s, the author and his colleagues Steven E. Petersen, Michael I. Posner, Peter T. Fox, Julie Fiez, and Mark Mintun began their own imaging and behavioral experiments of word reading (Petersen et al., 1988, 1989, 1990; Raichle et al., 1994a; Shulman et al., 1997b). It is from these published experiments that the data presented here have in part been culled.

A key feature of the experiments is their hierarchical design. In concert with most other functional imaging studies, the strategy here compares images of blood flow obtained with PET in a control state to those obtained when the brain is engaged in a task of interest (for a more detailed review of the strategy and its physiological basis

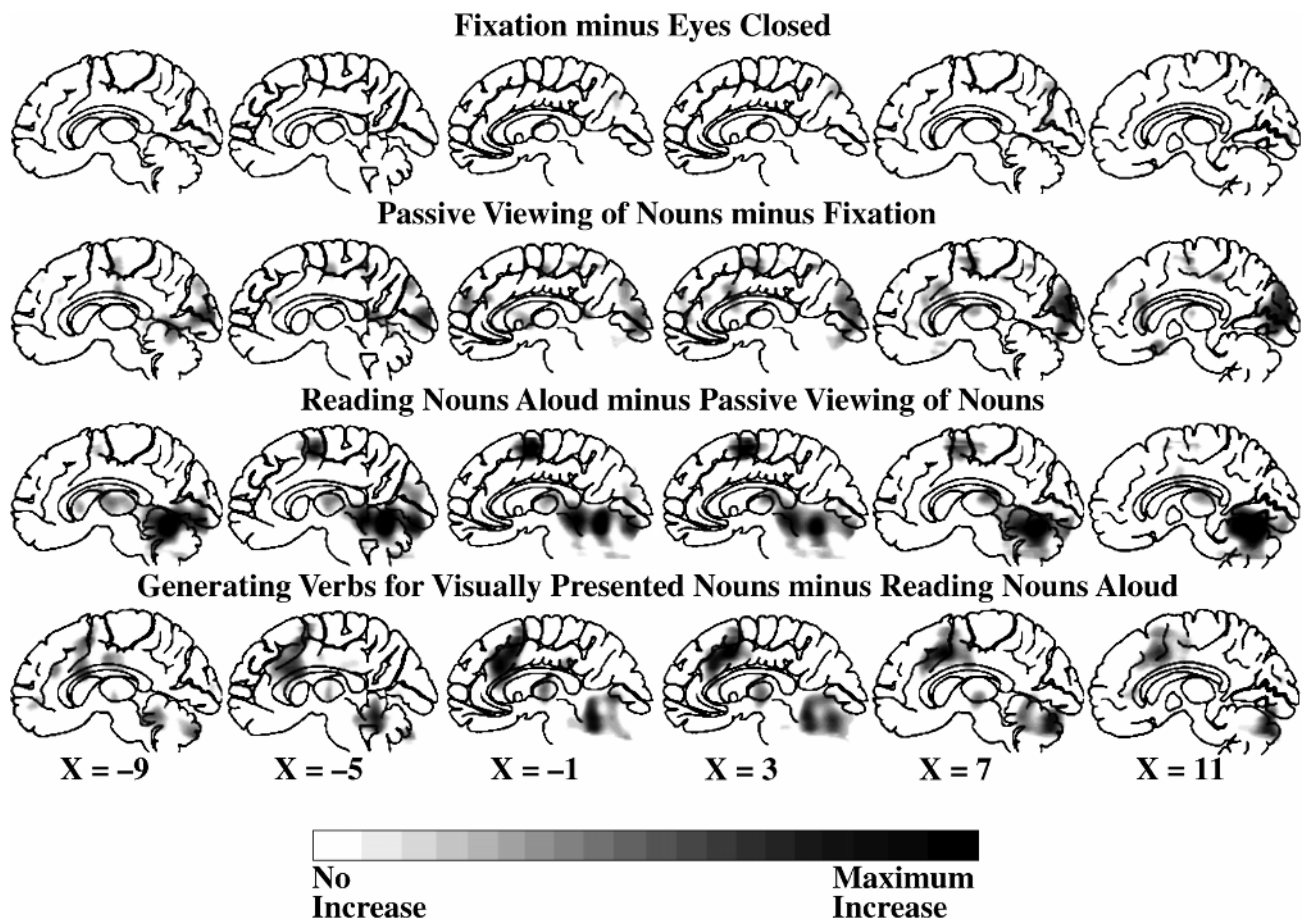

FIGURE 91.2 Data identical to that shown in figure 91.1 except that it is presented in the sagittal plane. These images be-

see Raichle, 1998). The five behavioral states include: (1) awake, alert, with eyes closed, performing no task; (2) maintaining visual fixation on a television monitor containing only a fixation point; (3) maintaining visual fixation on a television monitor while common English nouns are presented just below the point of fixation; (4) reading aloud the nouns as they are presented; and (5) speaking aloud an appropriate use or verb for each noun as it is presented. In the initial experiments (Petersen et al., 1988, 1989) the words were presented 60 times per minute and were on the monitor for 500 ms. In the later experiments (Raichle et al., 1994b) the words were presented 40 times per minute, again for 500 ms each. English was the native language of the subjects and they were all skilled readers. The behavioral state comparisons to be discussed in this chapter include 2 versus 1, 3 versus 2, 4 versus 3, 5 versus 4, and 5_{practiced} versus 5_{naive}.

Observations

Figure 91.1 illustrates, in horizontal sections, the areas of the brain that *increase* their activity (i.e., blood flow) in

gin 9 millimeters to the left of the midline ($X = -9$) and end 11 millimeters to the right of the midline ($X = 11$).

association with incremental increases in the complexity of a simple word reading task. Figure 91.2 is a sagittal representation of the information in figure 91.1 and more clearly depicts the changes occurring along the midline in parietal and frontal cortices.

As shown in the first row of figure 91.1, opening the eyes and maintaining fixation on a small crosshair on an otherwise blank television monitor results in activation of visual cortex as compared to resting quietly with eyes closed. The images in the second row of figures 91.1 and 91.2 represent those additional areas of the brain that become active when common English nouns appear on the screen. The subjects' instruction was simply to maintain fixation. Multiple areas within visual cortices become active when words are presented even though no specific processing of these words has been requested. Much effort has been devoted to an analysis of changes such as these (Fiez and Petersen, 1998; Howard et al., 1992; Petersen et al., 1990; Price, Wise, and Frackowiak, 1996; Price et al., 1994), but the results have so far been inconclusive.

The images in the third row of figures 91.1 and 91.2 reflect those areas of the brain associated with the motor

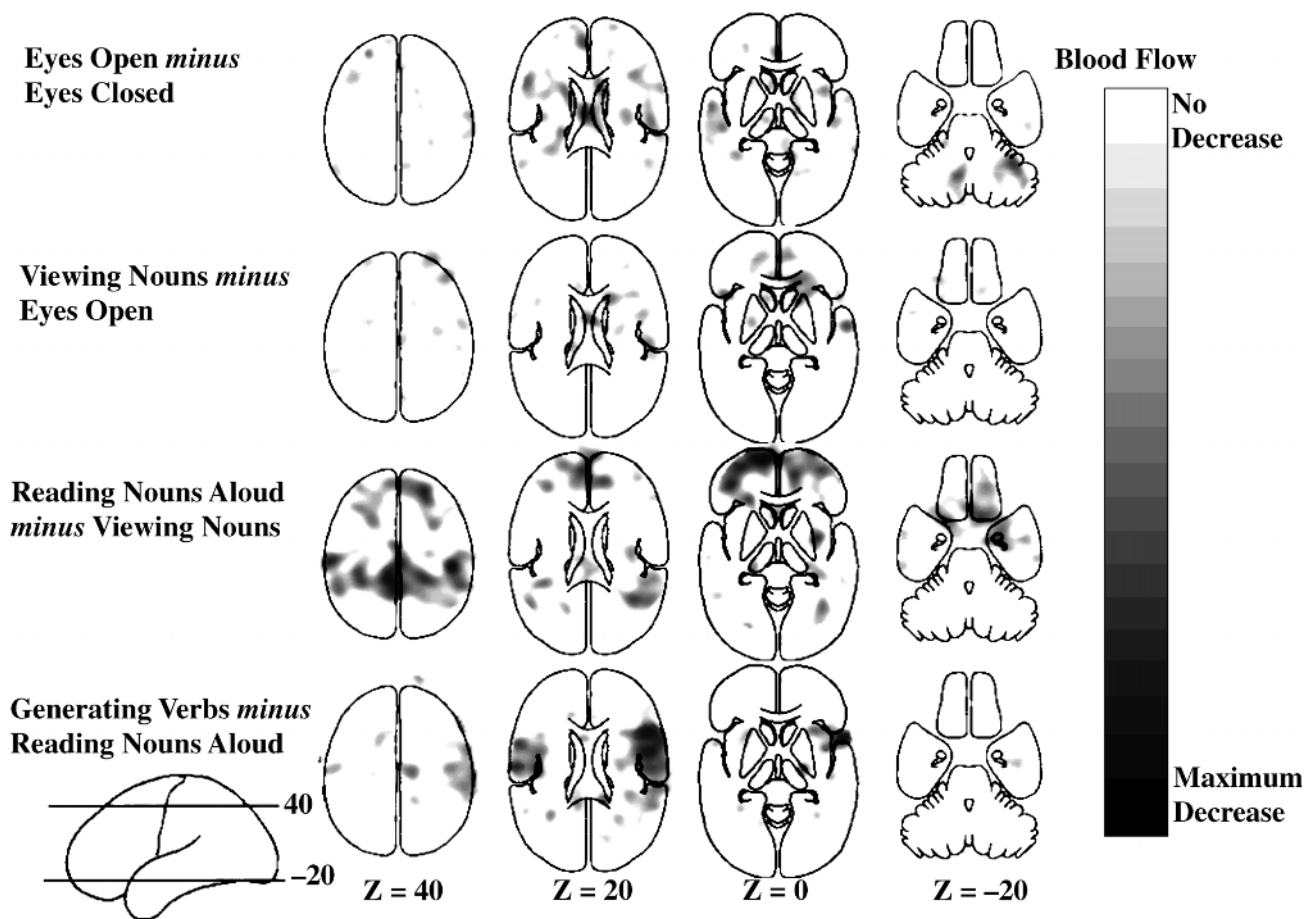

FIGURE 91.3 Hierarchically organized subtractions involving the same task conditions as shown in figure 91.1, with the dif-

ference that these images represent areas of *decreased* activity in the task condition as compared with the control condition.

aspects of reading words aloud. Not surprisingly, these include the primary motor cortices bilaterally, the supplementary motor cortex (best seen along and anterior midline in figure 91.2) and the paramedian cerebellum. There was also prominent activity over sylvian-insular cortices bilaterally (figure 91.1, row 3, $Z = 20$).

Finally, the images in the fourth row of figures 91.1 and 91.2 reflect those additional areas of the brain active during verb generation. These include the anterior cingulate cortex (best seen in figure 91.2), the left prefrontal cortex, the left temporal cortex, and the right hemisphere of the cerebellum. The latter finding was a particular surprise because the subtraction producing this image had eliminated all of the motor aspects of speech production.

Reviewing all of the changes in figures 91.1 and 91.2, it is possible to appreciate those associated with the perfected skill of word reading (i.e., the first three rows) and those changes associated with the much more difficult and novel task of verb generation. It should be noted that all subjects performing verb generation initially found it difficult. This was reflected in a much slower voice onset

latency and a failure to supply verbs for all nouns in order to keep pace with the task (Raichle et al., 1994a).

The data presented in figures 91.1 and 91.2 illustrate nicely a hierarchical dissection of word reading in terms of the way regions of the brain increase their activity in support of the component processes involved. In keeping with the thesis of this chapter, it is tempting to assume that areas of the brain added in support of the verb generation task (i.e., row four, figures 91.1 and 91.2) become candidates for those concerned with task-associated consciousness. But before making such an assumption, it is important to appreciate a bit more fully additional changes taking place in brain organization—changes that are not revealed in these two figures. To set the stage for a presentation of these changes, we first examine one of the major criticisms of the subtractive logic leading to the images in figures 91.1 and 91.2.

The strategy employed in the experiments depicted in figures 91.1 and 91.2 was introduced in 1868 by the Dutch physiologist Franciscus C. Donders (cf. Donders, 1969). Donders proposed a general method to measure thought processes based on a simple logic. He

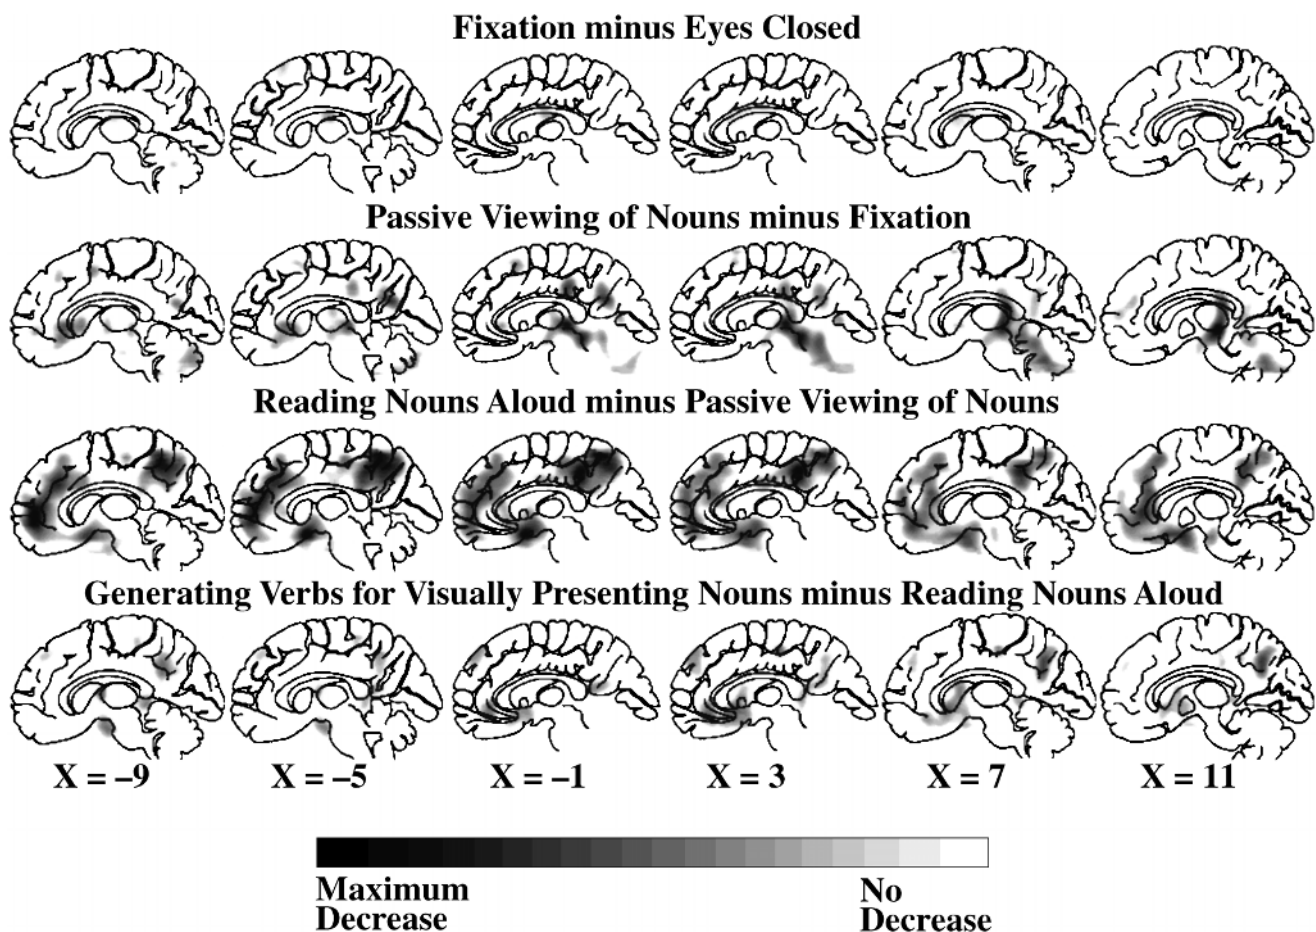

FIGURE 91.4 Data identical to that shown in figure 91.3 except that it is presented in the sagittal plane. The slices are positioned as noted in figure 91.2.

subtracted the time needed to respond to a light (say, by pressing a key) from the time needed to respond to a particular color of light. He found that identifying the color of the light required about 50 ms. In this way, Donders isolated and measured a mental process for the first time by subtracting a control state (i.e., responding to a light regardless of its color) from a task state (i.e., discriminating the color of the light). It is the same logic that is now applied in the experiments presented in figures 91.1 and 91.2.

One criticism of this approach has been that the time necessary to press a key after a decision to do so has been made is affected by the nature of the decision process itself. By implication, the nature of the processes underlying key press, in this example, may have been altered. Although this issue (known in cognitive science jargon as the *assumption of pure insertion*) has been the subject of continuing discussion in cognitive science, it finds a resolution in functional brain imaging, where changes in any process are directly signaled by changes in observable brain states.

Careful analysis of the changes in the functional images reveals whether processes (e.g., specific cognitive operations) can be added or removed without affecting ongoing processes (e.g., motor processes). This is accomplished by examining the data not only for areas activated during the course of a particular cognitive paradigm but also those that become deactivated. An analysis of regional deactivations is presented in figures 91.3 and 91.4. Figure 91.4 is a sagittal representation of the information in figure 91.3 and more clearly presents changes occurring along the midline of the brain in parietal and orbital frontal cortices. By examining the images in figures 91.1–91.4 *together*, we gain a much more complete picture of the dramatic changes taking place in the word reading paradigm under analysis here.

Finally, in order to exploit fully the paradigm depicted in figures 91.1–91.4 for the purpose of identifying candidate regions of the brain concerned with task-related consciousness, it is important to assess the effect of practice on the regions uniquely recruited in the verb generation task (row 4, figure 91.1). As we have previously

FIGURE 91.5 Changes in activity resulting from practice on the verb generation task include decreases (top row) and increases (bottom row) in brain activity.

demonstrated (Raichle et al., 1994a), a brief period of practice on the verb generation task results in a significant reduction in voice onset latency (i.e., subjects are simply able to respond more quickly when seeing the same noun on multiple occasions). In addition, responses become stereotyped, with the same verb being chosen each time a particular noun is presented. These changes in performance are associated with dramatic changes in the brain regions supporting task performance. The brain changes associated with practice are illustrated in figures 91.5 and 91.6. In these two figures it can be seen that anterior cingulate cortex (and associated dorsal medial frontal cortices), left prefrontal cortex (including the left and right frontal operculum), left temporal cortex, and right cerebellum (not as well shown; see Raichle et al., 1994a, for more details)—all active during naïve verb generation—return to baseline.

Activity in the ventral medial frontal cortex, reduced in the naïve condition (see figure 91.3, rows 3 and 4), is actually reduced even further after practice. Regional activity within sylvian-insular cortices, active during word reading (figure 91.1, row 3, $Z = 20$) yet inactivated during naïve verb generation (figure 91.3, row 4, $Z = 20$), are now reactivated, especially on the right side. Finally, midline activity within the region of the precuneus

and posterior cingulate cortex, while reduced from baseline during naïve word reading and verb generation (figure 91.4), increases in association with increased activity in visual cortices as the result of practice on the verb generation task (figure 91.6, row 2).

Discussion

The purpose of this exercise was to identify brain activity changes associated with task-related conscious behavior. The strategy involved comparing PET images of blood flow change obtained in a novel reading task (i.e., verb generation) with those obtained during a well-practiced task with identical perceptual and motor requirements (i.e., word reading). Additionally, comparisons were made between the naïve and practiced performance of the verb generation task itself. On these comparisons, it was hypothesized that regions of the brain concerned with conscious task performance could be isolated and identified. Consistent with this hypothesis, regional changes in brain activity associated with conscious, effortful performance of the verb generation task were identified. These included widely distributed regions of both increases and decreases in brain activity.

Practiced Verb Generation minus Naïve Verb Generation

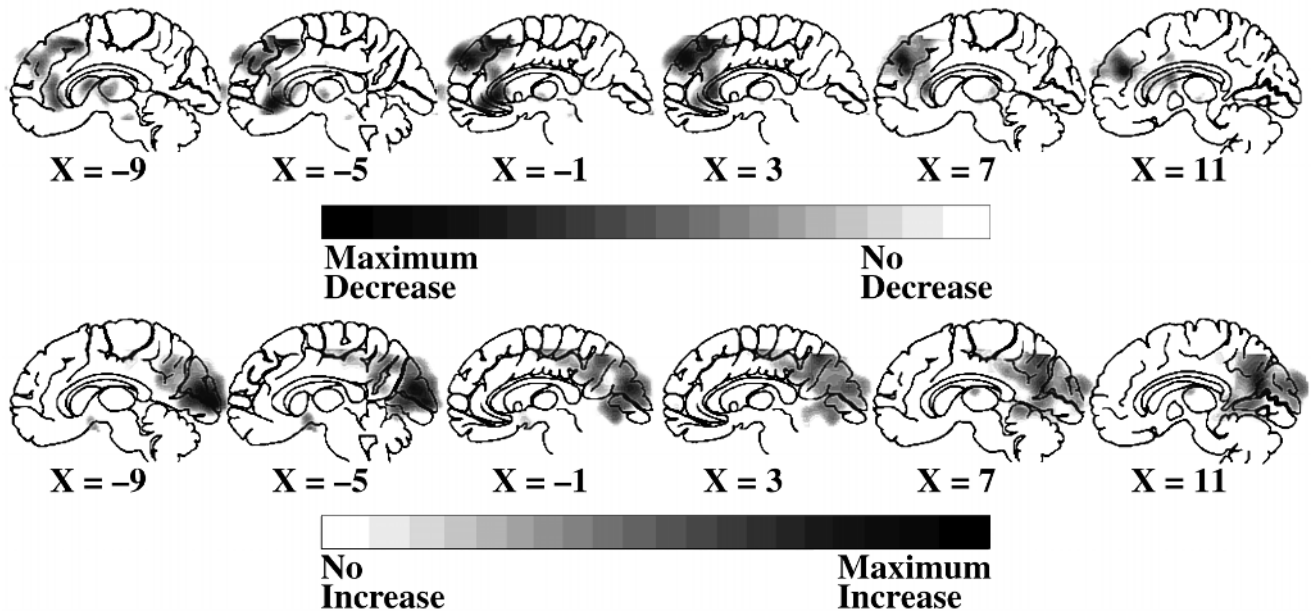

FIGURE 91.6 Data identical to that shown in figure 91.5 except that it is presented in the sagittal plane. The slices are position as noted in figure 91.2.

REGIONS OF INCREASED ACTIVITY When naïve performance of the verb generation task was compared to word reading, regions in anterior cingulate cortex, left prefrontal cortex, left temporal cortex, and the right cerebellar hemisphere were found to exhibit increased activity. Consistent with our hypothesis that these regions are uniquely associated with the conscious performance of this task, their activity ceased with practice, which both produced significant improvement in performance and elicited stereotyped responses (Raichle et al., 1994a). Changes in the opposite direction in sylvian-insular cortices bilaterally offered further support for the unique role of these regions in conscious task performance (Raichle et al., 1994a). Thus, regions active during naïve task performance disappeared with practice whereas regions within sylvian-insular cortices bilaterally, inactive during naïve task performance, become active with practice. The reciprocal nature of these changes makes it unlikely that practice simply results in a more efficient use of regions always devoted to task performance.

Thus, reading aloud familiar words utilizes a pathway from word perception regions to speech production regions via regions in sylvian-insular cortices bilaterally. Prior to practice, a completely different pathway connects word perception regions to speech production regions. How are we to think about these two pathways and the circumstances under which they are utilized? What is their relationship, if any, to the several instantia-

tions of dual route ideas in speech production? What, if anything, does this have to say about conscious versus nonconscious behaviors?

To begin, the two routes revealed by our studies of the verb generation task (Petersen et al., 1988, 1989; Raichle et al., 1994a) would qualify for the two routes envisioned in Lichtheim's original theoretical formulation (Lichtheim, 1885; McCarthy and Warrington, 1984). Although probably first suggested by John Hughlings Jackson (Jackson, 1874), the idea of two pathways was advanced most clearly by Lichtheim, a Swiss neurologist. In an attempt to provide a conceptual framework for the various forms of aphasia reported by Broca, Wernicke, and others, he devised a scheme centered around three brain systems: an auditory word-form area concerned with the perceptual aspects of language; a center for the motor representations of words, or a motor center of speech; and a very distributed system "for the elaboration of concepts." As he envisioned it, information coming from the auditory word-form system could advance to the motor center for speech either directly or via the concept system. The latter route via the concept system he characterized as more "conscious" and less fluent than the former (see Lichtheim, 1885, p. 474). One pathway utilized a direct route from perception to production whereas the other utilized a more indirect route involving a distributed system of widely separated areas of the cerebral cortex.

In a very telling discussion Lichtheim said:

[I]t would appear as if, in naming objects, the auditory representations once found had to react in consciousness. This variety of language is a much more “conscious” one than fluent speaking, in which *we are aware of the sense of what we are saying, rather than of every word we say* [italics added]. Under certain circumstances conversational language is carried on in a similar way to naming, as, for instance, when we use an idiom not quite familiar to us. Here we must seek the words by the complicated process just mentioned; the direct communication between concept and motor center without cooperation of sound-representation does not exist; the subconscious act of speaking is not yet possible. A greater psychical exertion is obviously required, and consequently more fatigue is entailed. (Lichtheim, 1885, p. 474.)

Lichtheim also envisioned, presciently, that acquisition of language occurred by imitation, “as observed in the child, and upon the reflex arc which this process presupposes.” And he went on to say, “When intelligence of the imitated sounds is superimposed, a connection is established between the auditory center (for word-representations) and the part (of the brain) where concepts are elaborated.”

Shallice and Norman formulate such issues more generally in terms of what they call “contention scheduling” and a “supervisory attention system” (Shallice, 1988). *Contention scheduling* is the process by which selection is made of routine actions or thought processes. It is considered to be a decentralized process involving a very large but finite set of discrete programs, hierarchically organized. Routine activities of our daily lives, such as driving a car back and forth to work, are managed in a nonconscious manner through contention scheduling (Lichtheim, I am sure, would have used spontaneous speech as an example). A particular set of programs or schema has a level of activation dependent upon the triggering inputs it receives. While summarized nicely in Norman and Shallice’s model, this general idea has much support in the psychological literature (see the summary discussion, p. 333, in Shallice, 1988). We would suggest that, in the case of the verb generation paradigm (Raichle et al., 1994a), regions within sylvian-insular cortices represent some of the regions involved in the process of contention scheduling as formulated by Norman and Shallice.

This formulation of the functional organization of our mental lives is obviously incomplete. A moment’s reflection suggests that, useful as they may be under most circumstances, routine actions and thought processes are sometimes inappropriate, occasionally embarrassing, and potentially dangerous (Reason and Mycielska, 1982). Therefore, there has to be a means by which routine, reflexive behaviors and thoughts can be inhibited

and replaced, either transiently or permanently, by more appropriate behaviors and thoughts (Reason and Mycielska, 1982). Norman and Shallice (Shallice, 1988) postulate the existence of a second system—the supervisory attention system—to accomplish this.

The *supervisory attention system* provides a mechanism whereby elements or schema within the lower-level contention scheduling system for routine, reflexive behaviors and thoughts can be temporarily modified by activating or inhibiting particular elements within it. This facilitates coping with novel situations in which the routine selections are unsatisfactory. As Shallice states, “The primary function of the Supervisory System is that of producing a response to novelty that is planned rather than one that is routine or impulsive” (Shallice, 1988, p. 345). In a general sense, this fits nicely with Lichtheim’s concept of a center for the elaboration of concepts.

While both Lichtheim and Norman and Shallice envisioned a *superimposition* of higher centers for the conscious guidance of behavior over more routine, reflexive responses, our data would suggest a *substitution* of regions. In our example, regions guiding nonautomatic or conscious speech acts are preferentially selected, by a process yet to be defined, over those areas concerned with automatic or nonconscious speech acts when a well-learned, reflexive response like word reading is not appropriate. As a corollary, one must also envision circumstances in which the reverse is true: Automatic responses are preferred and, hence, selected. As Sutherland has pointed out, “[W]hen confronted by a predator, it is surely better to climb a non-optimal tree than to be eaten while weighing the respective merits of different trees” (Sutherland, 1996). The manner in which the brain is biased *either* way (i.e., toward or away from automatic behaviors) remains a most important and challenging question.

Lichtheim did not specify the neural correlates of his higher centers, but he was quite clear that he did not believe them to be housed in a single area. “Though in the diagram point B [see diagram 1, p. 436, in Lichtheim (1885)] is represented as a sort of center for the elaboration of concepts, this has been done for simplicities [sic] sake; with most writers, I do not consider the function to be localized in one spot of the brain, but rather to result from the combined action of the whole sensorial sphere. Hence, the point B should be distributed over many spots” (Lichtheim, 1885, p. 477).

Shallice and Norman were much more specific in drawing attention to the role of the frontal lobe in their supervisory attention system (Shallice, 1988). They review extensive evidence, primarily from neuropsychology, showing that patients with frontal lobe injury often act in an impulsive and reflexive manner as if they lacked a supervisory attention system.

Reviewing the evidence that has now been gained from functional imaging studies in normal subjects, one would have to conclude that both Lichtheim and Norman and Shallice were correct in anticipating brain regions uniquely involved in conscious, reflective behavior as distinct from regions concerned with reflexive, habitual performance. It is clear from the data presented in this chapter that multiple, widely distributed areas of the normal human brain—including the cerebellum—are involved in the performance of a novel speech production act, just as Lichtheim (1885) would have predicted. Likewise, it is also clear that the frontal lobe plays a role, although not an exclusive one, as Norman and Shallice implied.

The experiments used for illustrative purposes in this chapter and the work of Lichtheim (1885) focus specifically on language. The work of Norman and Shallice (Shallice, 1988) and of others (e.g., Passingham, 1993; Shiffrin and Schneider, 1977) suggests that the issues involved transcend any single domain of human performance.

Many analyses might conclude at this point with comments about the potential role of brain regions that *increase* their activity during reflective or novel task performance. However, our data suggest there is more to the story. To wit: While some regions of the brain increase their activity during novel task performance, others, just as dramatically, *decrease* their activity.

REGIONS OF DECREASED ACTIVITY When subjects become actively involved in word reading, whether reading aloud or generating verbs, multiple regions across both cerebral hemispheres show a significant decrease in activity (figures 91.3–91.6). These include regions along the midline in orbitofrontal cortex, posterior cingulate cortex, and precuneus, which have been noted to decrease in a wide variety of tasks (for details of a large meta-analysis of such changes, see Shulman et al., 1997b). Characteristic of the experiments in which these particular decreases are regularly seen are ones in which subjects must actively process a visual stimulus. The control state is one in which the same stimulus is passively viewed. Additionally, decreases should also be noted in sylvian-insular cortices bilaterally. These appear only in naïve verb generation and not in word reading, where increases are actually observed (figure 91.1, row 3, $Z = 20$).

What are we to make of these reductions? Physiologists have long recognized that individual neurons in the cerebral cortex can both increase or decrease their activities from a resting, baseline firing pattern depending on task conditions. Decreases, however, seem to have received somewhat less attention. Nevertheless, examples

of decreases abound in the neurophysiological literature (e.g., Georgopoulos et al., 1982). A parsimonious view of these decreases in neuronal activity is that they reflect the activity of inhibitory interneurons acting within local neuronal circuits of the cerebral cortex. Because inhibition is energy-requiring (Ackerman et al., 1984; Batini et al., 1984; Biral et al., 1984), it should be impossible to distinguish inhibitory from excitatory cellular activity on the basis of changes in either blood flow or metabolism. Thus, on this view, a local increase in inhibitory activity is just as likely to increase blood flow and the fMRI BOLD signal as a local increase in excitatory activity. How, then, might decreases in blood flow as seen with PET (figures 91.3–91.6) or the fMRI BOLD signal arise?

To understand the significance of the decreases in blood flow in a functional imaging experiment, it is important to distinguish two separate conditions in which they might arise. The usual circumstance accounting for reductions in activity arises when two images are compared, one containing a regional increase in blood flow caused by some type of task-induced activity while the other does not.

Let us consider, for example, the increase in activity over the sylvian-insular cortices that occurs when individuals read a word aloud as compared to viewing the same word passively. This is seen bilaterally in figure 91.1, row 3, at $Z = 20$. Turning to figure 91.2, row 4, note that we now observe a reduction in activity in almost the same region as subjects perform, naïvely, verb generation as compared to reading aloud. What has occurred is that images in which the region is activated (i.e., word reading) are subtracted from images in which the region is not activated (i.e., verb generation). These results suggest that this region is used in automatic speech production such as word reading, not for a novel reading task like verb. However, as verb generation becomes more automatic, this region is reactivated (figure 91.4, row 2, $Z = 20$ and $Z = 0$).

The second circumstance in which decreases in blood flow and the fMRI BOLD signal are observed is not due to data manipulations of the type just described. Rather, blood flow and the fMRI BOLD signal actually decrease regionally from a *baseline state* for that region. The immediate question that arises is, how is such a baseline state defined. How, for instance, is it to be distinguished from just another activation state? The definition arises from a consideration of the metabolic and circulatory events surrounding the activation of a typical cortical region (for a recent review see Raichle, 1998) and how these differ from the metabolism and circulation of the baseline state of the awake human brain.

Measurements in the normal, adult, awake human reveal a brain that consumes approximately 0.27

micromoles of glucose and 1.54 micromoles of oxygen per gram of tissue per minute (Siesjo, 1978). This is supplied by a blood flow of approximately 0.55 milliliters of blood per gram of tissue per minute (Siesjo, 1978). While these values vary from one region of the brain to another (e.g., the average values in white matter are typically one-fourth that of gray matter), the *relationship* among them remains remarkably constant. As a consequence, the fraction of available oxygen removed by the cerebral cortex of the resting brain from circulating blood (i.e., the oxygen extraction fraction or OEF) is quite uniform.

What, then is so distinctive about areas of increased activity? The answer lies in the deviations from these baseline relationships. One might assume that an increase in local cellular activity in the cerebral cortex would be accompanied by a proportionate increase in blood flow and oxygen consumption. This would be reflected in an unchanged OEF. However, this is not observed (Fox and Raichle, 1986; Fox et al., 1988). Blood flow actually increases substantially in excess of any increase in oxygen consumption, leading to a significant decrease in the OEF. The direct correlate of this is a local increase in the ratio of oxyhemoglobin to deoxyhemoglobin as oxygen supply exceeds demand. It is the local increase in the oxyhemoglobin:deoxyhemoglobin ratio that forms the basis for the fMRI signal. This fMRI signal usually is referred to as the BOLD (blood oxygen level dependent contrast) (Ogawa et al., 1990; Ogawa et al., 1992; Kwong et al., 1992).

Positive BOLD contrast is now routinely seen by investigators worldwide doing functional brain imaging studies with fMRI. There is a remarkable correspondence between the location of BOLD contrast and changes in blood flow measured with PET when the same tasks are studied (for a recent review see Raichle, 1998). This correspondence has become routine confirmation of the fact that blood flow changes in excess of any change in oxygen consumption during changes in the functional activity of the cerebral cortex.

We are now in a position to ask a rather obvious question. What is the baseline-state metabolic and circulatory status of brain regions that exhibit a reduction in blood flow and a negative BOLD contrast when subjects actively engage in task performance? The regions of particular interest are those seen along the midline in figures 91.3–91.6 and previously noted to behave similarly across a wide variety of visual attention tasks (Shulman et al., 1997b). For these medial regions of orbital frontal and posterior cingulate/parietal cortex, the OEF does not differ significantly from the overall brain average in the baseline state (data from 20 normal adult controls; unpublished observations of M. E. Raichle, A.-M. Mac-

Leod, W. Drevets, and W. J. Powers) whereas the blood flow, oxygen consumption, and glucose utilization significantly exceed the brain average. Remarkably, the region of the posterior cingulate and adjacent precuneus is actually the metabolically most active region of the cerebral cortex in the resting brain (data from 20 normal adult controls; unpublished observations of M. E. Raichle, A.-M. MacLeod, W. Drevets, and W. J. Powers).

The above analysis leads to the inescapable conclusion that anterior as well as posterior regions of the cerebral hemispheres, particularly prominent but not exclusively along the midline, are intensely active during the baseline state of the awake brain (e.g., eyes closed or passive viewing of a television monitor and its contents). With focused attention on a variety of tasks (e.g., see Shulman et al., 1997b, and figures 91.3–91.6) these regions exhibit a conspicuous reduction in activity. What makes the active state of these regions so distinctive is that it is characterized by metabolic and circulatory relationships that typify baseline, not functionally activated cerebral cortex. It is as if these areas of the brain are uniquely active as a *default baseline state of the conscious resting brain*.

Several additional general comments about these decreases from a baseline state should be made. First, they are not, as some have informally suggested, merely the hemodynamic consequence of increases elsewhere (i.e., an intracerebral “steal” phenomenon). Such a hypothesis is very unlikely to be correct because of the tremendous hemodynamic reserve of the brain (Heistad and Kontos, 1983) and also because there is no one-to-one spatial or temporal correlation between increases and decreases (see figures 91.1–91.6).

Second, they are not confined to regions of the brain whose baseline activity significantly exceeds that of the overall brain average. For example, it has been shown that, in anticipation of stimulation, areas of somatosensory cortex outside the representation of the skin area that is the target of the expected stimulation exhibit marked reductions in activity as measured with PET (Drevets et al., 1995). These observations are thought to reflect a model of spatial attention in which potential signal enhancement relies on a generalized suppression or filtering of background activity (Whang, Burton, and Shulman, 1991).

Third, the relatively large spatial extent of these regional decreases suggests the inactivation of specific systems within the cerebral cortex. The mechanism(s) by which this is achieved remains to be determined. What is most important for our present purpose is identifying the functions with which these regions are associated. Whatever the functions, it seems reasonable to suggest that they must be suspended for proper task execution.

With regard to the posterior cingulate and adjacent precuneus, animal studies suggest that it is involved in orientation within and interpretation of the environment (for a review see Vogt, Finch, and Olson, 1992). The response of posterior cingulate neurons to visual stimuli, for example, is crucially dependent upon the physical characteristics of the stimulus. Small spots of light to which a monkey may be attending and responding do not elicit neuronal responses in this area. In contrast, large, brightly textured stimuli elicit responses even if they are totally irrelevant to tasks the animal is performing. Lesions of the posterior cingulate also disrupt spatial working memory. From the studies reviewed by Vogt and his colleagues (1992), it is not possible to separate, cleanly, spatial working memory functions from functions concerned with evaluation and interpretation of the environment.

Additional light is shed on the function of the posterior cingulate cortex and adjacent precuneus by the work of Carol Colby (Colby et al., 1988) and John Allman (Baker et al., 1981). Both of these studies call attention to the fact that elements of the dorsal stream of extrastriate visual cortex (area M in the owl monkey and area PO in the macaque) are part of a network of areas concerned with the representation of the visual periphery. These areas are primarily located along the dorsal midline and can be distinguished in various ways, experimentally, from those areas of the visual system of the monkey that represent the fovea (i.e., the central 10 degrees of the visual field). From these data and those reviewed by Vogt and colleagues (1992) emerges a specific hypothesis: Activity within the posterior cingulate cortex and adjacent precuneus in the baseline state in humans is associated with the representation (monitoring) of the world around us (i.e., our environment or our visual periphery). The hypothesis further predicts that efficient processing of items in the center of our visual field requires generalized suppression or filtering of this background activity (Whang et al., 1991). This is operationally achieved by reducing activity of the posterior cingulate and precuneus. As has been shown by Shulman and colleagues (1997a), attention to centrally presented stimuli is accompanied by enhanced responses in areas of the visual system concerned with their processing at the same time that posterior cingulate and precuneus are shut down (Shulman et al., 1997b).

Behavioral evidence in humans provides additional support for the above hypothesis. Mackworth (1965) has shown that increased foveal load leads to decreased extrafoveal information acquisition. He termed this phenomenon "tunnel vision." This work has been confirmed and extended by a number of workers (e.g., see Henderson and Ferreira, 1990). Older adults are actually more af-

fected by foveal load than younger adults (Owsley, Ball, and Keeton, 1995). While no studies have been done to relate this decrement in performance with normal aging to reductions in the activity of the posterior cingulate and adjacent precuneus, recent studies in patients with Alzheimer's disease provide an intriguing perspective.

As reported recently by Kuhl and his associates (Minoshima, Foster, and Kuhl, 1994; Minoshima et al., 1997) reduction in the activity of the posterior cingulate gyrus is the earliest metabolic abnormality detected by PET in patients with Alzheimer's disease. Abnormalities in the processing of extrafoveal information have been noted in patients with dementia of the Alzheimer's type (Benson, Davis, and Snyder, 1988), but no systematic study has been performed on this group of patients in light of the recent findings of Kuhl and his associates (Minoshima et al., 1994, 1997).

Finally, severe damage to parietal cortex when it extends medially to include precuneus and the posterior cingulate produces a condition known as Balint's syndrome (Hecaen and Ajuriaguerra, 1954) whose cardinal feature is the inability to perceive the visual field as a whole (i.e., severe tunnel vision). This is known as simultanagnosia (Rizzo and Robin, 1990). It is of interest that simultanagnosia has been reported in patients with dementia of the Alzheimer's type (Benson et al., 1988). Of interest would be a study of the relationship between decrements in baseline metabolic activity in this region in patients with Alzheimer's disease and the development of simultanagnosia.

Thus, posterior cingulate and adjacent precuneus cortex can be hypothesized as a region of the brain associated with the continuous gathering of information about the world around us. It would appear to be a default condition of the brain with rather obvious evolutionary significance. Successful performance on tasks requiring focused attention demands that such broad information gathering be curtailed. We see this reflected in marked decreases in this region during focused attention. As a task becomes easier and requires less focused attention, activity in this area predictably resumes (figure 91.6, row 1).

The other midline region of the cortex exhibiting prominent decreases in activity during focused attention is orbitofrontal cortex. As with the posterior cingulate and adjacent precuneus, these changes have been observed not only in the tasks discussed in this chapter but also in a wide variety of other tasks requiring focused attention (Shulman et al., 1997b). In contrast to the behavior of the posterior cingulate and adjacent precuneus, the decreases we observe in orbitofrontal cortex not only decrease initially when reading tasks are novel and require focused attention, but actually decrease even

further with practice (figure 91.6, row 2). Further analysis of these changes (Simpson et al., 1997) reveals a number of important features. First, the reductions observed in this region, as they increase with practice, are significantly correlated with improved performance as measured by improved reaction times on the verb generation task. Second, these changes represent correlated responses within a group of areas in orbital and medial inferior prefrontal cortex and the hypothalamus. This is consistent with the connectional anatomy of this region known from nonhuman primates (Carmichael and Price, 1994, 1995, 1996). Third, the likelihood that these changes are related to the emotional aspects of novel task performance is supported by a parallel study of anticipatory anxiety in normal subjects (Simpson et al., 1997). Reductions similar to those seen in the verb generation task were correlated with the degree of anxiety reported by the subjects. Less anxious subjects showed greater reductions in activity.

These observations occur against a background of considerable clinical and experimental data suggesting that orbital and medial prefrontal cortex plays an important role in emotional behavior (Drevets et al., 1997), especially fear (for a review see LeDoux, 1996) and decision making (Bechara et al., 1997; Damasio et al., 1994). These activities are based on converging information from multiple sensory modalities (Rolls and Baylis, 1994) and connections to amygdala, hypothalamus, brainstem, and basal ganglia (Carmichael and Price, 1996). Puzzling, of course, is the fact that the changes we observe are seen as reductions and, as discussed in detail earlier, they begin from a baseline level of activity which is significantly above the brain mean.

A broad view of the function of the prefrontal cortex suggests that it is active when new rules need to be learned and older ones rejected (Dias, Robbins, and Roberts, 1997; Wise, Murray, and Gerfen, 1996). The activation of regions within prefrontal cortex during the naïve performance of the verb generation task (figure 91.1, row 4) would certainly be consistent with that view. When this same reasoning is applied to orbital and medial prefrontal cortex, one must confront the fact that activity in this region may be greatest in the baseline state. Thus, as we come to associate general monitoring of incoming sensory information with the posterior cingulate and adjacent precuneus, we may also come to associate an evaluation of this information with the medial and orbital frontal cortices.

Conclusions

The main purpose of this chapter was to present a functional brain imaging strategy that isolates potential neu-

ral correlates of consciousness in humans. This strategy is based on skill learning. In the example presented (rapidly generating verbs for visually presented nouns), a cognitive skill is examined before and after practice. As shown, there are marked qualitative differences in the neural circuitry supporting performance of this task in the naïve and practiced state. As pointed out, William James succinctly captured the interpretation we wish to place on this transformation in performance and neural circuitry: “Habit diminishes the conscious attention with which our acts are performed” (James, 1890). Areas active during naïve performance become candidate neural correlates of consciousness.

The neural correlates of consciousness for one task may not correspond, region for region, to those for another task. This is most directly demonstrated in our own data when comparisons are made between verb generation and maze tracing (Petersen et al., 1998). Thus, while a common theme emerges from the work reviewed here in terms of principles governing the neural instantiation of conscious and nonconscious behavior of the same task, differences do exist among tasks in terms of the specific brain regions involved. Put another way, no single, unique architecture emerges as a unifying feature of conscious, reflective performance (see also Shulman et al., 1997b).

The cerebral cortex appears like the sections of a symphony orchestra. No one section or individual is at all times necessary for the production of the music. Likewise in the brain, no one region (system) necessarily specifies the content of consciousness under all circumstances. Rather, it is a distributed process with changing participants allocated by need. Some of those participants are identified through the strategy described. Relationships determine performance and performance can be infinitely variable.

The continuity of consciousness awareness must also be kept in mind in pursuing the type of analysis presented in this chapter. Consciousness is not terminated when naïve task performance ceases. In this regard, it is important to consider the role of brain regions whose activity ceases during naïve task performance only to resume under baseline conditions or practiced task performance. These task-induced deactivations from a baseline state provide equally important clues about the neural correlates of the content of consciousness. The recognition of these decreases and, as a consequence, a better understanding the baseline state, probably represent a unique contribution of functional brain imaging to our understanding of human cortical physiology. These findings should stimulate increased interest in the manner in which brain resources are allocated.

ACKNOWLEDGMENTS The material in this chapter was presented, in part, as the 1997 Thomas William Salmon Lecture of the New York Academy of Medicine. I thank my many colleagues whose published data I have reviewed in this chapter. I also thank the National Institutes of Health, The McDonnell Center for Studies of Higher Brain Function of Washington University, The John T. and Katherine T. MacArthur Foundation, and the Charles A. Dana Foundation for generous support over many years.

92 Prefrontal Cortex, Time, and Consciousness

ROBERT T. KNIGHT AND MARCIA GRABOWECKY

ABSTRACT A central feature of consciousness is the ability to control the fourth dimension, time. Humans can effortlessly move their internal mental set from the present moment to a past remembrance and just as easily project themselves into a future event. It is proposed that this capacity to extract oneself from the present and fluidly move forward or backward in time is dependent on the evolution of the human prefrontal cortex. Prefrontal cortex modulates activity in multi-modal association and limbic cortices through widely distributed inhibitory and excitatory pathways. Prefrontal cortex also has a selective bias to novelty, crucial for detecting change and hence for the correct temporal coding of events. These extensive modulatory pathways coupled with an intrinsic link to temporal coding provide a mechanism for rapid engagement of distributed neural networks critical for seamless transitions through the time continuum. Support for this hypothesis is found in the fact that prefrontal damage results in a failure in the ability to extract oneself from the present. Indeed, the hallmark of the severe prefrontal syndrome is perseveratory and stimulus-bound behavior—a classic example of a failure in temporal control.

The massive evolution of the prefrontal cortex parallels the development of many distinctively human behaviors. One central feature of human cognition is the ability to go “off-line” to self-consciously monitor one’s own behavior. Effective self-monitoring requires rapid comparison of behaviors and outcomes from one’s past in order to make predictions about present and future situations. Through its extensive reciprocal connections, the human prefrontal cortex is uniquely suited to control self-monitoring processes. The prefrontal cortex has been shown to be involved in inhibitory and excitatory control of large-scale neural systems, and it exhibits a response bias toward novelty. Predictably, prefrontal damage results in deficits in both inhibitory gating and excitatory modulation together with failures in the detection and production of novelty. Thus, the prefrontal patient functions in a noisy internal milieu and is lacking in appropriate clues to new versus old information.

ROBERT T. KNIGHT Department of Psychology, University of California, Berkeley; Veterans Medical Center, Martinez, Calif.

MARCIA GRABOWECKY Department of Psychology, Northwestern University, Evanston, Ill.

In addition, the prefrontal patient’s difficulties with excitatory modulation of connected brain regions lead to a breakdown in working-memory abilities (Baddeley, 1992a,b).

These physiological problems manifest behaviorally as reduced decision confidence, failure in sustaining neural activity over delays, and deficits in the proper ordering of past, present, and future events. Lack of executive control of internal and external events results in a variety of deficits in planning and memory organization. Perhaps as important a problem is the failure to effectively recruit large-scale neural ensembles for self-monitoring and self-direction across the time domain. It is proposed that consciousness is dependent on the ability to rapidly switch between an internal and external milieu—an ability that permits one to remove from the present and construct and compare alternative interpretations of past, present, and future events. This off-line ability to consciously evaluate and adjust behavior along the time continuum is crucially dependent on lateral prefrontal cortex.

Jacobsen’s (1935) seminal report of delayed-response deficits in sulcus principalis-lesioned monkeys provided a landmark observation for insight into the role of prefrontal cortex in integrative behavior. The delayed-response deficit was initially thought to reflect a simple memory problem. Subsequent research in the 1940s revealed that a problem with the inhibition of extraneous inputs was a major contributor to the delayed-response deficit, leading to the formulation of the distractibility hypothesis of prefrontal function (Malmö, 1942; Bartus and Levere, 1977). This theory postulates that prefrontal patients are unable to suppress response to irrelevant stimuli during both sensory and cognitive processing. Inhibitory deficits are found in neurological patients with dorsolateral prefrontal damage and in schizophrenic patients with prefrontal hypometabolism, providing support for the prefrontal-distractibility hypothesis. In addition to inhibition of task-irrelevant distractors, successful delay performance requires selective excitatory engagement and integration of activity in diverse brain regions dependent on task-specific

parameters. Single-unit data in monkeys, electrophysiological data in normal controls and prefrontal-lesioned patients, and cerebral blood flow data from normals have all shown that combined prefrontal-posterior association cortex activation is required to perform difficult tasks that entail bridging a delay.

Damage to dorsolateral prefrontal cortex (Rajkowska and Goldman-Rakic, 1995a,b) results in a distinct set of cognitive disturbances (Damasio, 1985; Knight, 1991). In early disease from tumors or degenerative disorders or in cases of unilateral structural damage from stroke or tumor, subtle deficits in creativity and mental flexibility can be observed. When unilateral disease progresses or becomes bilateral, pronounced behavioral deterioration emerges. Well characterized problems with attention, planning, temporal coding, metamemory, judgment, and insight predominate. In advanced bilateral dorsolateral prefrontal damage, perseveration (manifesting as being “stuck” in the present) and primitive reflexes (including snout, grasp, and palmomental reflexes) emerge.

An invariable consequence of prefrontal damage is a decreased confidence about many aspects of behavior. Prefrontal patients are often uncertain about their performance despite objective evidence to the contrary. The prefrontal patient’s inability to selectively inhibit unwanted input results in a noisy internal milieu; and this, coupled with an inability to detect deviance, hampers the ability to properly code spatiotemporal information. Lacking the ability to maintain a temporal stream and reach decisions with appropriate levels of confidence, the prefrontal patient has no coherent past or future; he or she is locked in an uncertain present characterized by perseveration and stimulus-bound behavior. The neurophysiological and neuropsychological evidence supporting these conclusions will be reviewed in turn.

Neurophysiological studies

INHIBITORY CONTROL

Inhibition in animals Prefrontal inhibitory control of neural activity in multiple brain regions has been reported in a variety of mammalian preparations. Net inhibitory control to both subcortical (Edinger, Siegel, and Troiano, 1975) and cortical regions has been documented (Alexander, Norman, and Symmes, 1976; Skinner and Yingling, 1977). Sensory transmission is under constant modulation. Galambos (1956) provided the first physiological evidence of an inhibitory pathway in mammals with the description of the brainstem auditory olivo-cochlear bundle. The olivo-cochlear bundle projects from the olivary nucleus to the cochleus in the

inner ear. Stimulation of the bundle results in inhibition of transmission from the peripheral cochlea to the brainstem cochlear nucleus, as measured by reductions in evoked responses in the auditory nerve. This research revealed that mammalian nervous systems employ inhibitory connections to regulate sensory flow in small-scale systems. Subsequent studies reported evidence of inhibition in larger neuronal networks. Motor control studies revealed that movement induces sensory gating from the spinal cord to the primary cortical receptive zone (MacKay and Crammond, 1989). In an elegant series of experiments, Skinner and Yingling reported evidence of a multi-modal prefrontal-thalamic sensory gating system in cats. Cryogenic blockade of this prefrontal-thalamic gating system resulted in enhancement of amplitudes of evoked responses in primary sensory cortices (Skinner and Yingling, 1977; Yingling and Skinner, 1977).

This prefrontal-thalamic inhibitory system provides a mechanism for intermodality suppression of irrelevant inputs at an early stage of sensory processing. The system is modulated by an excitatory prefrontal projection to the nucleus reticularis thalami. This nucleus reticularis thalami in turn sends inhibitory GABA-ergic projections to all sensory relay nuclei, providing a potential neural substrate for selective sensory filtering (Guillery, Feig, and Lozsadi, 1998). This system provides a powerful neural substrate for early suppression of extraneous inputs, permitting more effective focusing of attention. In addition to obvious behavioral relevance, this gating system conserves energy expenditure since irrelevant inputs are blocked at an early level of processing.

Inhibition in prefrontal patients The attention deficits observed in prefrontal patients have been linked to problems with inhibitory control of posterior sensory and perceptual mechanisms (Lhermitte, 1986; Lhermitte, Pillon, and Serdaru, 1986). Event-related potential (ERP) studies document inhibitory failure in prefrontal lesioned patients. Recordings of ERPs to irrelevant auditory and somatosensory stimuli (monaural clicks or brief electric shocks to the median nerve) in patients with dorsolateral prefrontal damage provide physiological evidence of a deficit in inhibitory control. Evoked responses from primary auditory (Kraus, Ozdamar, and Stein, 1982) and somatosensory (Sutherling et al., 1988) cortices were recorded from these patients and age-matched and non-prefrontal-damaged controls (figure 92.1). Stimuli consisted of either monaural clicks or brief electric shocks to the median nerve eliciting a small opponens pollicis twitch. Prefrontal damage produced disinhibition of both the primary auditory and somato-

FIGURE 92.1 Primary cortical auditory and somatosensory evoked potentials are shown for controls (solid line) and patients (dashed line) with focal damage in the lateral parietal cortex (top, $n = 8$), temporal-parietal junction (middle, $n = 13$) or dorsolateral prefrontal cortex (bottom, $n = 13$). Reconstructions of the center of damage in each patient group are shown on the left. Somatosensory evoked responses were recorded from area 3b (N20) and areas 1 and 2 on the crown of the post-central gyrus (P26). Stimuli were squarewave pulses of 0.15 ms duration delivered to the median nerve at the wrist. Stimulus intensity was set at 10% above opponens twitch threshold and stimuli were delivered at a rate of 3/s. Damage in posterior cortical regions sparing primary somatosensory cortex had no

effect on the N20 or earlier spinal cord potentials. Prefrontal damage resulted in a selective increase in the amplitude of the P26 response (hatched area). Auditory stimuli were clicks delivered at a rate of 13/s at intensity levels of 50 dB HL. Unilateral damage in the temporal-parietal junction extending into primary auditory cortex reduces P30 responses. Lateral parietal damage sparing primary auditory has no effect on P30 responses. Dorsolateral prefrontal damage results in normal inferior collicular potentials (wave V) but an enhanced P30 primary cortical response (hatched area). The shaded area in each modality indicates the area of evoked potential amplitude enhancement. (Adapted from Knight, 1994.)

sensory evoked responses (Knight, Scabini, and Woods, 1989; Yamaguchi and Knight, 1990). Spinal cord and brainstem potentials were not affected by prefrontal damage, suggesting that the amplitude enhancement was due to abnormalities in either a prefrontal-thalamic or a prefrontal-sensory cortex mechanism. Damage to primary auditory or somatosensory cortex reduced the early latency (20–40 ms) evoked responses generated in these regions. Posterior association cortex lesions that spared the primary sensory regions had no effect on early sensory potentials and served as a brain-lesioned control group (see figure 92.1).

Chronic sensory disinhibition contributes to the behavioral sequelae noted after prefrontal damage. For in-

stance, decision confidence, a hallmark of prefrontal disease, is decremented by a noisy internal milieu. Distractibility has been proposed to be a major component of the delayed-response deficit in animals with prefrontal lesions (Bartus and Levere, 1977; Brutkowski, 1965; Malmö, 1942). Inability to suppress irrelevant information is associated with difficulties in target detection and match-to-sample paradigms in prefrontal patients. For example, patients with frontal resections are impaired at detecting multiple visual targets embedded among distractors (Richer et al., 1993) and in suppressing information in memory and Stroop tasks (Shimamura et al., 1995; Vendell et al., 1995). Likewise, patients with lesions confined to dorsolateral prefrontal cortex are

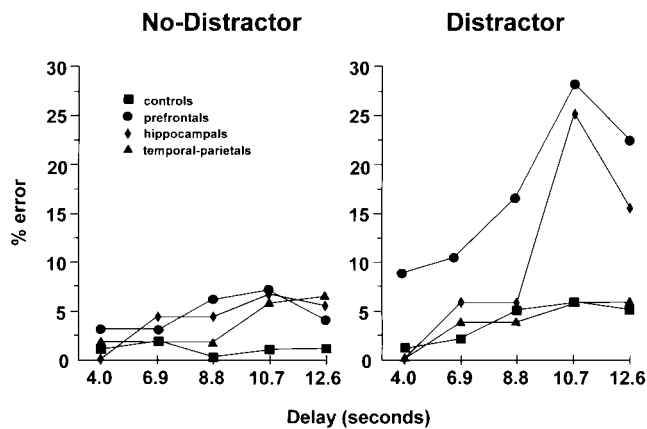

FIGURE 92.2 Mean percentage error for the three patient groups and age-matched controls in the no-distractor and distractor conditions (from Chao and Knight, 1995). Note the marked decrement in performance of the prefrontal patients in the presence of distractors. Similar to monkeys, hippocampal region-damaged patients are affected by distractors only at longer ISIs.

impaired in simple delay tasks requiring matching of two environmental sounds only when distractors intervene between cue and target.

Prefrontal lesioned patients were tested on an auditory delayed match-to-sample task. Subjects reported whether a cue (S1) and a subsequent target sound (S2) were identical. On some trials, S1 and S2 were separated by a silent period. On other trials, the delay between S1 and S2 was filled with irrelevant tone pips. As noted above, prefrontal patients were impaired behaviorally by distractors and generated enhanced primary auditory cortex-evoked responses to these irrelevant tones (Chao and Knight, 1995, 1998; see figure 92.2).

Inhibition in psychiatric patients There is extensive literature supporting prefrontal dysfunction in schizophrenics. Findings suggestive of altered dorsolateral prefrontal function include evidence from both cerebral blood flow (Weinberger, Berman, and Zec, 1986; Weinberger et al., 1992) and post-mortem studies (Akbarian et al., 1995, 1996). Schizophrenics are also reported to have a physiological deficit in inhibitory control. Freedman and colleagues developed the P50 auditory gating paradigm to study inhibitory control in schizophrenics. In normals, presentation of a pair of clicks at a short inter-stimulus interval decreases the amplitude of the evoked response to the second stimulus. Freedman reported that the second stimulus in a pair of auditory pulses did not habituate in schizophrenics (Freedman et al., 1983). This electrophysiological finding supported the long-standing proposal that schizophrenics fail to properly

filter extraneous inputs (McGhie and Chapman, 1961; Venables, 1964). The P50 gating deficit is reliably seen in a significant percentage of nonpsychotic relatives of schizophrenics and has been proposed to be a neurophysiological trait for schizophrenia. Phenotypic segregation of schizophrenics and first-order relatives using the P50 gating paradigm has been employed in recent genetic studies. This research has isolated a putative schizophrenia gene localized to chromosome 15q13-14 which controls alpha 7 nicotinic receptor expression (Freedman et al., 1997).

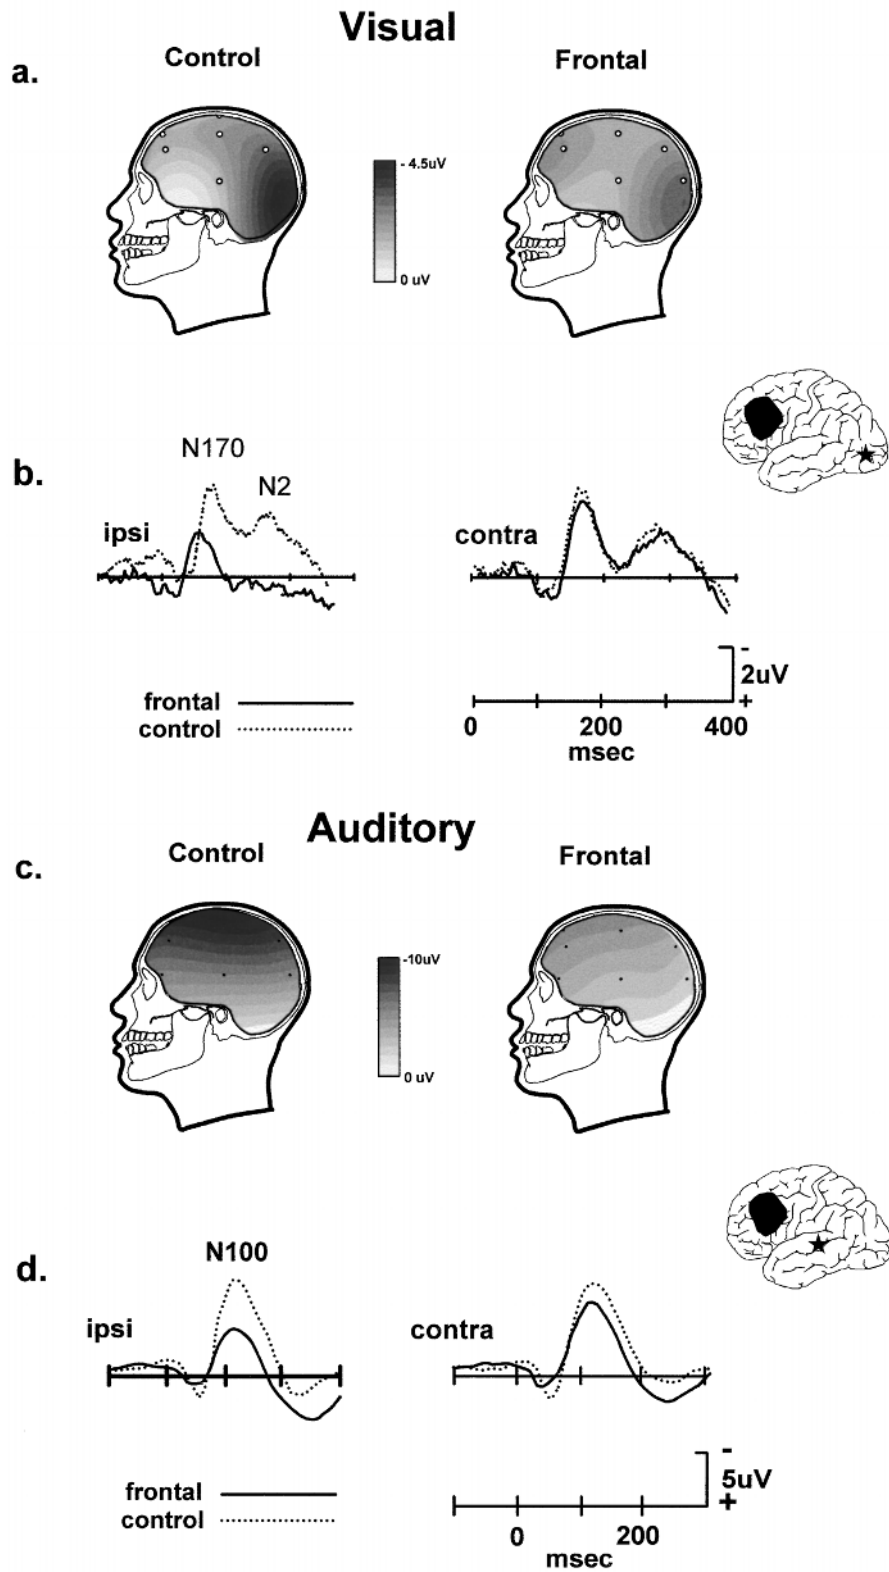

The neural network controlling P50 gating is of both theoretical and clinical relevance. We examined the P50 gating deficit in patients with dorsolateral prefrontal damage and in age-matched controls (see figure 92.3). An initial study has shown that elderly control subjects ($n = 9$) have normal suppression of the second stimulus in an auditory pulse pair. Prefrontal patients ($n = 8$) failed to suppress the amplitude of the second stimulus in the ear contralateral to prefrontal damage (Knight et al., 1998). This suggests that prefrontal cortex dysfunction may underlie or contribute to the P50 schizophrenic gating deficit.

EXCITATORY CONTROL

Excitation in prefrontal patients In addition to suppressing response to irrelevant stimuli, subjects must sustain neural activity in distributed brain regions in order to attend to and correctly perform delay and working-memory tasks. Neural modeling employing prefrontal excitatory modulation of distributed brain regions has successfully modeled several prefrontally mediated behaviors and prefrontal dysfunction in schizophrenia (Cohen, Braver, and O'Reilly, 1996). Neurological patients with focal prefrontal damage provide further physiological evidence of failure in excitatory control of

FIGURE 92.3 (a) Topographic maps display the scalp voltage distribution of the N170 generated to targets in a visual detection task for controls and prefrontal patients. The extrastriate focus of the N170 is reduced ipsilateral to prefrontal damage. The shaded area on the brain shows the area of lesion overlap, while the star indicates a putative generator location of the N170 in extrastriate cortex. (b) Group-averaged ERPs for target stimuli in controls and prefrontal patients ($n = 11$); waveforms are from posterior temporal electrodes (T5/T6 in controls), and ipsilateral (ipsi) or contralateral (contra) to lesion. (c) Topographic maps and (d) waveforms from an auditory delayed match to sample paradigm in controls and frontals ($n = 10$). There is a prominent intrahemispheric decrease in the auditory N100 generated to the S1 and S2 stimuli in the matching paradigm. (Adapted from Swick and Knight, 1998.)

EXCITATORY MODULATION

posterior association cortex in patients with prefrontal damage.

Reduced neural activity in extrastriate visual association cortex is also observed after prefrontal damage (Knight, 1997a; Swick and Knight, 1998). Visual stimuli elicit a prominent, attention-sensitive N170 (N1) scalp potential maximal in amplitude over temporal-occipital sites (Mangun and Hillyard, 1988; Mangun, 1995). Topographic and dipole modeling studies indicate an N170 source in extrastriate cortex (Gomez-Gonzalez et al., 1994). The influence of prefrontal cortex on the visual N170 has been examined in both linguistic and nonlinguistic tasks. In one experiment, controls and frontal patients performed a visual detection task requiring detection of an infrequent target embedded in a series of irrelevant background and novel stimuli (Knight, 1997a). Dorsolateral prefrontal damage decreased visual N170 amplitude for all stimuli in the lesioned hemisphere. N170 was normal in the nonlesioned hemisphere. Maximal reductions were seen at posterior temporal sites over extrastriate cortex (figure 92.2b). N170 reductions in frontal patients are also observed for verbal stimuli (Swick and Knight, 1998). Subjects read words and pronounceable nonwords and performed either lexical decision or recognition memory tasks. As in the detection experiment, N170 amplitude was reduced over extrastriate recording sites ipsilateral to prefrontal damage.

The visual experiments indicate that dorsolateral prefrontal cortex provides an ipsilateral facilitatory input to neural processing in extrastriate cortex which enhances neural activity within 120 ms post-stimulus. Further support for prefrontal modulation of visual processing in extrastriate areas during sustained attention and spatial memory performance comes from blood flow data in humans (Roland, 1982), network analyses of PET results (McIntosh et al., 1994), and single-unit and lesion data in monkeys (Fuster, 1985; Funahashi, Bruce, and Goldman-Rakic, 1993). Projections from prefrontal areas 45 and 8 to inferior temporal (IT) areas TE and TEO have been demonstrated in monkeys (Webster, Bachevalier, and Ungerleider, 1994). This provides a putative pathway by which prefrontal cortex could exert facilitatory influence on activity in posterior visual association cortex. A similar failure of prefrontal excitatory modulation is observed in the auditory modality. In the delayed match-to-sample task discussed above, both the S1 and S2 stimuli generated a prominent N100 ERP response, which reflects neural activity in auditory association cortex (Woods, 1990). Prefrontal lesions markedly reduced the N100 component throughout the hemisphere ipsilateral to damage (figure 92.3c,d). There are well described prefrontal projections to the superior temporal plane

which may subserve this excitatory input (Alexander, Newman, and Symmes, 1976).

The auditory and visual data provide clear evidence that dorsolateral prefrontal cortex is crucial for maintaining distributed intrahemispheric neural activity during auditory and visual attention-dependent tasks. These results are also in accord with findings that patients with prefrontal lesions are impaired in their ability to focus attention on task-relevant stimuli (Fuster, 1989; Knight et al., 1981; Damasio, 1985; Woods and Knight, 1986).

Sustained attention in normals Hillyard and colleagues (1973; Hillyard and Picton, 1987) reported that focused attention to tones in one ear resulted in an enhancement of evoked potentials to all stimuli in that ear. This enhancement onset occurred at about 50 ms post-stimulation and was sustained for at least 200 to 500 ms. These electrophysiological results provided critical information to attention theorists. First, stimulus discriminability was shown to be dependent on the degree of attention-related evoked potential enhancements, providing a link between physiology and attention in humans. Second, the early onset of the attention modulation provided clear evidence of an early sensory filtering mechanism in humans, addressing the long-standing early vs. late selection controversy (Broadbent, 1958; Kahneman and Treisman, 1984; Treisman, 1960). Subsequent work has shown that the effects of attention can onset as early as 25 ms after stimulation, indicating that humans are able to exert attention effects on inputs to the primary auditory cortex (McCallum et al., 1983; Woldorff and Hillyard, 1991). Early onset selective attention effects have also been reported in the visual and somatosensory modalities (Desmedt, Hut, and Bourguet, 1983; Woods, 1990). In the visual modality attention may not modulate primary sensory activity in calcarine cortex, but instead acts on subsequent stages of processing in visual association cortices (Gomez-Gonzalez et al., 1994; Mangun, 1995).

Sustained attention in prefrontal patients Normal subjects generate robust attention effects for left- or right-ear stimulation. Left prefrontal patients have slightly reduced attention effects in both ears. A different pattern is observed after right prefrontal damage. Right prefrontal patients show electrophysiological and behavioral evidence of a dense hemi-inattention to left-ear stimuli (Knight et al., 1981). These data are in accord with the human hemi-neglect syndrome, which is more common after right prefrontal or temporal-parietal lesions (Kertesz and Dobrolowski, 1981; Mesulam, 1981). One theory states that the contralateral neglect observed after temporal-parietal or prefrontal right hemisphere lesions

is due to innate hemispheric attention asymmetries. The left frontal lobe is proposed to be capable of allocating attention only to the contralateral right hemispace, whereas the right frontal lobe can allocate attention to both the contralateral and ipsilateral hemispace. Thus, neglect is mild or not apparent after left-hemisphere lesions, since the intact right hemisphere is capable of allocating attention to both hemispaces. Dense contralateral neglect is seen after right hemisphere damage since the left hemisphere is incapable of allocating attention to the left hemispace (Mesulam, 1981).

Increased size of the right frontal lobe in humans may provide the anatomical substrate for the hemi-inattention syndrome in humans (Wada, Clarke, and Hamm, 1975; Weinberger et al., 1982). Posterior association cortex lesions in the temporal-parietal junction have comparable attention deficits for left- and right-sided lesions, indicating that these areas are not asymmetrically organized for auditory selective attention (Woods, Knight, and Scabini, 1993). This suggests that the left hemineglect syndrome subsequent to right temporal-parietal damage may be due to remote effects of disconnection from asymmetrically organized prefrontal regions.

Attention capacity is enhanced at short versus long interstimulus intervals in prefrontal lesioned patients. This could be due either to a problem with temporal bridging or to a distractibility deficit. Prefrontal cortex is necessary for bridging temporal discontinuities (Fuster, 1989). Thus, attention deficits at longer interstimulus intervals might be due to temporal bridging problems. However, at longer interstimulus intervals prefrontal subjects are also more likely to encounter intervening irrelevant stimuli. ERP-behavioral experiments provide evidence supporting the distractibility hypothesis. In normal subjects, delivery of an irrelevant stimulus in a nonattended ear during a dichotic listening experiment has no effect on attention effects to a subsequent stimulus in the attended ear. However, presentation of an irrelevant stimulus in the nonattended ear impairs detection of a subsequent stimulus in the attended ear in prefrontal patients. This effect is particularly pronounced in the ear contralateral to a prefrontal lesion at long interstimulus intervals. Since attention performance at long interstimulus intervals improves in the absence of distracting irrelevant stimuli, the results favor distractibility as the major contributor to prefrontal attention deficits (Woods and Knight, 1986).

NOVELTY

Overview The ability to detect and respond to new information is highly evolved in humans. In lower mammalian species, detection of and response to deviant environmental events are critical for survival (Sokolov,

1963). In humans, novelty detection remains crucial for the orienting response. However, the ability to process novelty has evolved into a central parameter for many other cognitive processes, such as memory and creativity. In the 1930s, Von Restorff reported that discrete novel stimuli are remembered better (Von Restorff, 1933). Subsequent behavioral-electrophysiological experiments confirmed that stimulus distinctiveness enhances recall (Karis, Fabiani, and Donchin, 1984).

Novelty has a powerful effect on memory for everyday events outside of the laboratory setting. Infrequent personal events—say, the birth of a child or a death—are deeply encoded. Similarly, rare but engaging external events, such as assassinations, are also better remembered. Several factors influence this effect. For instance, repetition of the news of Kennedy's assassination drives deep encoding. However, many individuals distinctly remember the first moments in which they were informed about Kennedy's death, often recalling exact details of what they were doing when they heard the news. Novelty influences other human behaviors, as well. Creative behavior is commonly defined in direct relation to the degree of novelty. The relationship between novelty and creativity extends to many endeavors, including art and science.

The neural mechanisms both of novelty detection and the generation of novel behaviors have stimulated increased interest in recent years. Multiple experimental approaches have focused on the biological mechanisms of novelty processing. Genetic studies of novelty-seeking behavior in humans have provided a link to the short arm of chromosome 11 and the dopamine D4 receptor gene (Benjamin et al., 1996; Ebstein et al., 1996). Neuropsychological, electrophysiological, and cerebral blood flow techniques (Knight and Scabini, 1998) have revealed that a distributed neural network including dorsolateral prefrontal cortex, temporal-parietal junction, hippocampus, and cingulate cortex is engaged both by novelty detection and during the production of novel behaviors. The data supporting these contentions will be reviewed.

ERPs, fMRI, and voluntary attention In everyday life, humans continually detect and respond to discrete environmental events. Subjects may allocate attention to a discrete event either voluntarily or automatically. Examples of voluntary attention might include simple tasks, such as looking for a pencil on your desk, or more complicated tasks, such as finding one key reference in a large pile of papers. Both tasks involve the ability to maintain a template of what you are looking for and to mount an appropriate behavioral response when that template is matched. During voluntary attentive search, distinct scalp recorded ERPs are generated to a correctly

detected stimulus. In the 1960s, researchers began to employ scalp-recorded event-related potentials (ERPs) to study a wide range of sensory and cognitive processes, including attention, motor performance, memory, and language. In 1965 two separate laboratories described the generation of a large positive parietal maximal scalp potential (P300), peaking in amplitude 300–500 ms after stimulus delivery, when a subject voluntarily detected a task-relevant event (Desmedt, Debecker, and Manil, 1965; Sutton et al., 1965). This ERP is referred to as a P3b response to distinguish it from scalp positive potentials (P3a) generated by novel stimuli. P300 responses to task-relevant targets (P3b) and task-irrelevant novel stimuli (P3a) are generated in all sensory modalities. P3b responses can even be recorded to the detection of a missing stimulus in a train of irrelevant stimuli.

Researchers studying voluntary attention have operationalized detection behavior to the “oddball task.” In the oddball task a subject is asked to detect an infrequent and low-probability event. The detected or target stimulus is referred as the “oddball” stimulus in a series of background stimuli. Detection of the oddball generates a prominent parietal maximal P3b. Theories focused on attention and memory have been proposed to account for the cognitive basis of the P3b, although no clear consensus has emerged (Donchin and Coles, 1988; Verleger, 1988). The most widely held view is that the P3b indexes updating of activity in corticolimbic circuits during voluntary attention and working memory (Ruchkin et al., 1992). Other proposals such as those linking P3b and template matching may also be subsumed under the concept of context updating in working memory (Chao, Nielsen-Bohman, and Knight, 1995). There is an extensive literature on the P3b, including electroencephalographic and magnetoencephalographic work in normals, intracranial ERP data from epileptic patients, and lesion and neuropharmacological studies in humans and animal models. These will not be reviewed in detail since several extensive reviews are available (Picton, 1995; Swick, Kutas, and Neville, 1994). The basic conclusion is that a distributed circuit including multi-modal posterior association cortex, hippocampus, cingulate cortex, and prefrontal cortex is engaged during voluntary detection tasks. The degree of prefrontal activation as measured by ERPs (Swick, 1998; Swick and Knight, 1999) or blood flow techniques (D’Esposito et al., 1994; Owen, Evans, and Petrides, 1996; Petrides et al., 1993a,b) increases with task difficulty and may be minimal when employing easy detection tasks.

Recent event-related fMRI studies have provided converging evidence on P3b sources. Visual or auditory studies have reported differing combinations of inferior

parietal, superior temporal plane, thalamic, and cingulate activations to correctly detected oddballs. Inferior parietal activation was reported by all groups. The degree of prefrontal activation has varied between different laboratories independently of the size of the magnet (Kirino et al., 1997; McCarthy et al., 1997; Menon et al., 1997). Although intracranial recording has provided clear evidence of generation of large hippocampal electrical fields to voluntarily detected stimuli (Smith et al., 1990; McCarthy et al., 1989), this activation is not readily apparent with fMRI. One possibility may relate to magnetic susceptibility effects. The authors of one report suggested that differences in sensitivity between ERP and fMRI techniques or differential degrees of sustained versus phasic activation in cortical versus hippocampal regions might also contribute to lack of significant activation of the hippocampus (McCarthy et al., 1997).

ERPs and novelty For several decades after Von Restorff’s seminal contribution on the relationship of novelty and memory performance, relatively little attention was directed to the underlying neural basis of this powerful effect. This changed in the mid-1970s with the publication of two papers reporting generation of scalp potentials to novel or deviant stimuli (Courchesne, Hillyard, and Galambos, 1975; Squires, Squires, and Hillyard, 1975). Involuntary orientation to an unexpected and novel stimulus generates a P300 response similar in some respects to that generated by a voluntarily detected stimulus. However, the novel response differs in three important aspects from the voluntary attention-related P3b. The novelty P300, referred to as a P3a, has a more frontocentral scalp distribution than the P3b, peaks 60–80 ms earlier in all sensory modalities, and undergoes rapid habituation over the first 5–10 stimulus presentations (Knight, 1984; Knight et al., 1989; Knight, 1997a; Yamaguchi and Knight, 1991a). Intracranial recordings of ERPs in the visual, auditory, and somatosensory modalities have documented that multiple neocortical and limbic regions are activated during tasks that generate scalp-recorded novelty-dependent P3a potentials (Baudena et al., 1995; Halgren et al., 1980, 1995a,b; Heit, Smith, and Halgren, 1990). Single-unit recording in humans has also reported novelty-related activity in the hippocampus (Fried, MacDonald, and Wilson, 1997).

Intracranial areas with novelty-related activity include frontal and posterior association cortex in addition to cingulate and mesial temporal regions. Scalp and intracranial novelty-related ERPs have been proposed to index neural activity in a distributed multi-modal corticolimbic orienting system that processes novel events (Courchesne, Hillyard, and Galambos, 1975; Knight, 1984; Squires, Squires, and Hillyard, 1975). Intracranial recordings in humans

have revealed that limbic-recorded voluntary attention and novelty ERPs have differential habituation properties (Knight and Scabini, 1998; Scabini and McCarthy, 1993). The hippocampal-recorded target ERP, like the scalp target P3b response, does not habituate over repeated detection of the attended stimulus (Knight and Scabini, 1998). Conversely, the hippocampal novelty ERP response, similar to its scalp electrophysiological P3a counterpart, undergoes rapid amplitude reduction over repeated trials (Knight, 1984; Yamaguchi and Knight, 1991a). These data support the claim that the novelty P3a is a central nervous system marker of the orienting response.

P300 potentials to both voluntarily detected stimuli and to unexpected task-irrelevant novel stimuli are recorded in multiple mammalian species including rats (Ehlers, Wall, and Chapin, 1991; Yamaguchi, Globus, and Knight, 1993), cats (O'Connor and Starr, 1985; Wilder, Farley, and Starr, 1981), dolphins (Woods et al., 1986), and monkeys (Arthur and Starr, 1994; Neville and Foote, 1984; Paller et al., 1988, 1992), supporting a broad ethological significance. The animal and human ERP work employing single-unit, field potential, lesion modeling, and neuropharmacological approaches has the power to delineate both the neural network and neural activity underlying novelty detection (Acquas, Wilso, and Fibiger, 1996; Burns et al., 1996; Feenstra, Botterblom, and Van Uum, 1995; Kitchigina et al., 1997; Metcalfe, 1993; Pineda, Foote, and Neville, 1989; Thinus-Blanc et al., 1996; Treves and Rolls, 1994).

Novelty and prefrontal patients Prefrontal cortex patients show impairments in both sustained and phasic attention (Knight, 1994). Neuropsychological testing has documented additional problems with the solving of novel problems (Godfrey and Rousseaux, 1997; Goldberg, Podell, and Lovell, 1994). Simple attention tasks are typically performed normally, but in advanced disease classic problems including indifference, loss of creativity, and deficits in orienting to novel stimuli and events emerge. In accord with these clinical observations, prefrontal damage results in differential effects on scalp P3a and P3b responses. The parietal P3b and concomitant behavioral performance in simple sensory discrimination tasks are unaffected by prefrontal damage. However, P3b reductions after prefrontal damage are observed in more complex tasks (Swick, 1998; Swick and Knight, 1999), supporting the notion of increasing prefrontal involvement with difficult tasks. Conversely, P3a responses to unexpected novel stimuli are markedly reduced by prefrontal lesions in the auditory (Knight, 1984; Knight and Scabini, 1998), visual (Knight, 1997a), and somatosensory modalities (Yamaguchi and Knight, 1991b, 1992), support-

ing a central role of prefrontal cortex in the processing of novelty (Godfrey and Rousseaux, 1997; Kimble, Bagshaw, and Pribram, 1965).

Novelty and mesial temporal-prefrontal dysfunction The hippocampal region is well known to be involved in memory encoding. The observation that stimulus novelty enhances memory encoding suggests that the hippocampus is likely involved in novelty processing. There is a long animal research literature linking the hippocampus with novelty or mismatch detection (Honey, Watt, and Good, 1998; Sokolov, 1963; Vinogradova, 1975). To address the question of the relationship of novelty and the hippocampus, we examined novelty detection capacity in patients with focal damage in the hippocampal region. The artery of Uchimura is a branch of the posterior cerebral artery that perfuses the hippocampal region (Uchimura, 1928). Damage from artery of Uchimura occlusion centers in the posterior hippocampal region, including hippocampus proper, dentate gyrus, subiculum, parahippocampal gyri, entorhinal cortex, and fornix (Eichenbaum, Otto, and Cohen, 1994). The fornix infarction results in macroscopic post-mortem atrophy of the mammillary body unilateral to fornix damage (Efanov, Knight, and Amaral, 1997). Mesial temporal infarction results in verbal and spatial memory deficits after left mesial temporal infarction and predominantly spatial nonverbal deficits after right-sided infarction (De Renzi, Zambolin, and Crisi, 1987; von Cramon, Hebel, and Schuri, 1988). Other deficits include problems with recognition and familiarity memory (Yonelinas et al., 1998) and failures in the binding of memory elements resulting in illusory memory conjunctions (Kroll et al., 1996).

Patients with posterior hippocampal region damage have normal parietal P3b activity and intact behavioral indices of detection ability. Conversely, frontocentral P300 activity to both target and novel stimuli is markedly reduced by hippocampal damage in all sensory modalities (Knight, 1996; see figures 92.4 and 92.5). These reductions are comparable to, and in some instances greater in amplitude than, those observed after focal frontal damage. The findings in the neurological patients support involvement of a prefrontal-hippocampal network in the detection of novelty in the ongoing sensory stream and suggest that the hippocampal formation has facilitory input into prefrontal cortex. Resting-state PET scans have documented frontal hypometabolism in patients with medial temporal amnesia (Perani et al., 1993), although no data are available for memory-related activation studies. Reciprocal intra- and interhemispheric pathways (Amaral, Inausti, and Cowan, 1993; Goldman-Rakic, Selemon, and Schwartz, 1984; Suzuki and Amaral, 1994) coursing through retrosplenial cortex or the cingulate (Shallice et

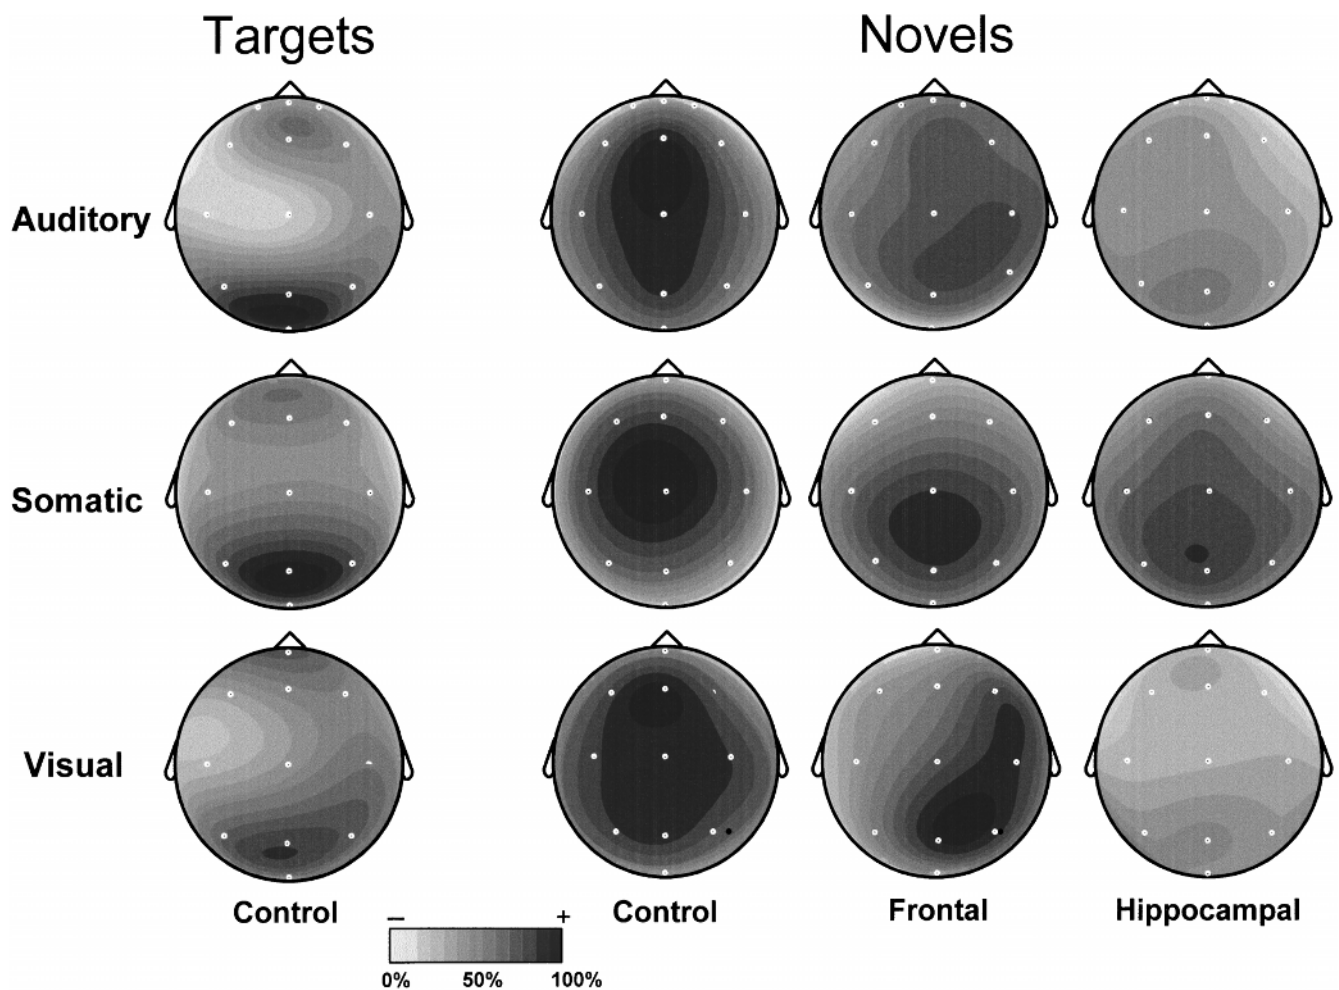

FIGURE 92.4 Scalp voltage topographies for target and novel stimuli in controls on the left. Note the marked increase in prefrontal activity to the novel stimuli in all sensory modalities. The effects of prefrontal or hippocampal lesions on the brain novelty response are shown on the right. Unilateral prefrontal damage results in multi-modal decrease in the novelty re-

sponse. Unilateral hippocampal damage results in severe bilateral reductions in the novelty response maximal at prefrontal sites. These findings implicate a prefrontal-hippocampal network in the detection of perturbations in the environment. (Adapted from Knight, 1997b.)

al., 1994) may provide the critical anatomical substrates for prefrontal-hippocampal interactions during novelty detection and memory processing. However, contributions from corticolimbic connections through entorhinal cortex or fornix-mammillothalamic-cortical pathways cannot be eliminated. Single-unit data in monkeys reveals that novelty-related cells in inferior temporal cortex fire within 100 ms (Miller, Li, and Desimone, 1991), suggesting that stimulus processing antecedent to P3a generation may contribute to novelty-related activation in humans.

PET and fMRI studies of novelty PET studies have shown that stimulus novelty activates distributed brain regions known to be engaged during memory storage (Tulving et al., 1996). Recently, fMRI has also been employed to study novelty. Generation of novel words activated the posterior hippocampus in the same area lesioned in the

hippocampal stroke patients with novelty ERP and SSR reductions (Stern et al., 1996). A study employing event-related fMRI techniques with a 1.5 T magnet failed to find significant visual novelty-related activation in either prefrontal or hippocampal regions, but did report posterior cortical activation (Kirino et al., 1997). Event-related fMRI research with a 4 T magnet has reported prefrontal and temporal activation to auditory novels (Turetsky, Al-sop, and Gur, 1997), and a study on a 3 T magnet also found novelty-related prefrontal and posterior cortical activation (Knight and Nakada, 1998).

Neuropsychological studies

Clinical neuropsychological tests fail to capture the behavioral changes associated with prefrontal damage. For instance, patients with large prefrontal lesions often

FIGURE 92.5 Group-averaged ERP data from controls and hippocampal-lesioned patients ($n = 7$) for auditory, visual, and somatosensory target and novel stimuli. Subjects were seated in a sound-attenuated booth and instructed to press a button upon detection of a designated target stimulus during each experiment. Auditory stimuli consisted of blocks of repetitive standard 1000-Hz monaural tone bursts (60 dB HL, 50 ms duration, 1 s ISI). Tone bursts of 1500 Hz occurred randomly on 10% of the trials and served as targets. Unexpected novel tones consisting of complex computer generated sounds and environmental noises such as bells or barks were randomly delivered on 10% of the trials. A similar paradigm was employed in the visual modality. Visual stimuli consisted of repetitive presentation of triangles. On 10% of the trials, inverted triangles served as target stimuli. On an additional 10% of trials, random line drawings or pictures of irrelevant stimuli served as novel events. Somatosensory stimuli consisted of repetitive taps to the index finger with targets being random taps to the ring finger that occurred on 10% of the trials. Novel stimuli consisted of brief random shocks to the median nerve on 6% of the trials. ERPs are shown from the electrode where maximal response were recorded (Pz for targets; Fz for novels). The novelty P3a is markedly reduced at prefrontal sites in all three modalities and the target P3b is spared. (From Knight, 1996.)

perform normally on standardized tests of memory and intelligence. Even the Wisconsin Card Sorting Test (WCST) commonly associated with frontal damage fails to effectively discriminate patients with frontal lesions from normals or those with lesions in other regions (Eslinger and Damasio, 1985; Grafman, Jonas, and Salazar, 1990). However, patients with prefrontal

cortex damage are impaired in the conduct of their daily lives. How can this paradox of good performance on standardized tests be reconciled with impaired functioning in daily life? Developments in the field of cognitive neuropsychology are beginning to provide important insights into the “prefrontal syndrome.”

THEORETICAL FRAMEWORK It is proposed that two classes of cognitive operations—simulation and reality checking—are disproportionately impaired after lateral prefrontal damage. *Simulation* refers to the process of generating internal models of external reality. These internal models may represent an accurate past or an alternative past, present, or future reality and can include models of the environment, of other people, and of the self. *Reality checking* refers to processes that monitor sources of information to develop accurate models of the form and context of internally and externally generated information. These monitoring processes are critical for discriminating between simulations of alternative possibilities and veridical models of the world. Simulation and reality checking can be considered “supervisory” (Shallice, 1988), “executive” (Baddeley and Wilson, 1988; Milner, 1982; Milner and Petrides, 1984; Stuss and Benson, 1986), or “organizational” functions (Duncan, 1986). Simulation and reality checking are essential for behavior to be integrated, coherent, and contextually appropriate—features that may be necessary for processing to become conscious (Allport, 1988). Both functions, acting in concert with other evaluative functions mediated by ventromedial and limbic structures, are required for behavior to be disengaged from current environmental constraints while simultaneously maintaining a representation of these constraints.

A patient lacking the ability to simulate alternatives to a situation is incapable of responding flexibly and becomes “stimulus-bound” (Luria, 1966; Luria and Homskaya, 1970). Without reality checking, a patient is incapable of discriminating between internally generated possible realities and the model of the external world as it currently exists. Simulation and reality checking work in concert, allowing humans to internally simulate manipulations of the external environment, evaluate the consequences of those manipulations, and act on the results of those simulations with a richer knowledge of potential outcomes. Rapid engagement of large-scale neural ensembles is required to achieve these goals. As previously posited, the prefrontal cortex is uniquely suited to perform this task.

It has been proposed that the frontal lobes are involved in decision making, goal-directed behavior, planning, and self-monitoring (Stuss and Benson, 1984, 1986; Stuss, 1991). Stuss and colleagues suggest that behavior is

controlled by a hierarchical process with three levels of activity. The first includes sensory-perceptual mechanisms that are located in posterior regions of the brain and tend to be modality-specific. Routinized operations are the rule in guiding sensory-perceptual behavior and the course of action is based on the demands of stimuli immediately present in the environment. An example is Shallice's proposal of a "contention scheduling" mechanism to associate overlearned inputs with routine actions (Shallice, 1988). The second level is that of executive functions. This level receives input from the sensory-perceptual level and is responsible for the direction of lower-level subsystems toward achievement of a goal. Control by the executive level is effortful in novel situations but, given sufficient practice, executive functions may become automatized. Simulation processes lie in the domain of executive functions. The highest level in this framework is that of consciousness and self-awareness. At this level a person maintains a self-image, with information about self-generated behavior integrated both over time and with the environment. Inputs to the level of self-awareness may include representations of the options generated by simulation processes operating at the executive level. Reality-monitoring activities are important at this level to allow an integrated model of the self to be maintained. In the following sections, evidence related to simulation and reality monitoring from normals and patients with frontal lobe impairments will be reviewed.

SIMULATION AND COUNTERFACTUALS

Overview Simulation processes have been extensively studied in normal populations (Kahneman and Miller, 1986; Kahneman and Tversky, 1972, 1982; Kahneman and Varey, 1990; Tversky and Kahneman, 1973, 1983). Judgments, including assessments of degree of satisfaction with an outcome and decisions about appropriate future actions, are made based on an evaluation of a set of internally generated alternatives. These are called counterfactual scenarios because they are alternative realities to the one objectively experienced. Counterfactual alternatives are omnipresent in normal human cognition and form a large and important part of our conscious awareness. Counterfactual expressions occur often in everyday life, especially in situations involving regret or grief. For example, a distraught parent may say, "If only I hadn't given my son the keys to the car! Then the accident wouldn't have happened." Such expressions reflect internally generated alternatives that seem very real to the person generating them. Of course, counterfactual alternatives occur in more mundane and less emotionally weighted situations as well. When, for instance, I say to myself, "If I'd ordered mari-

nara instead of white sauce, this stain on my tie would be even worse," I am generating a counterfactual scenario. Counterfactual alternatives play an important role in life satisfaction, with the most salient counterfactuals either increasing or decreasing satisfaction. For example, bronze medalists in Olympic competition tend to be happier than silver medalists, even though, objectively, the silver medalists have performed better (Medvec, Madey, and Gilovich, 1995). Presumably, this occurs because the most available counterfactual alternative for the bronze medalist is a worse outcome, finishing out of the medals, while the most available counterfactual outcome for the silver medalist is a better outcome, winning the gold.

According to Kahneman and Miller (1986), all events are compared to counterfactual alternatives. Events that recruit few alternatives, perhaps because they match the norm of similar events, are judged to have been predictable and unavoidable. Thus, even unanticipated events are seen as normal if they do not cause the generation of many counterfactual alternatives. It is proposed that patients with prefrontal damage are impaired in their ability to generate and evaluate counterfactuals, and that this problem may stem in part from a dysfunction in the automatic detection and generation of novelty. Because prefrontal patients do not respond appropriately to novel events, they may fail to process them appropriately. If the changes introduced by a new event are missed, the current situation will not be appropriately updated, and consequently, fewer counterfactual alternatives will be generated. Counterfactuals are constructed to compare what happened with what could have happened. Without such simulations, it is difficult to avoid making the same mistakes over and over again.

Stimulus-bound behavior Stimulus-bound behavior in patients with dorsolateral prefrontal lesions (Luria, 1966; Lhermitte, 1986) may be interpreted as a consequence of an inability to internally simulate situations differing from those specified by the current stimulus. For example, when objects are placed in front of a prefrontal patient, they are picked up and used without the patient's being asked to do so (termed "utilization behavior" by Lhermitte et al., 1986). In addition, the behavior of the experimenter may be imitated, even when this behavior is bizarre and socially inappropriate (Lhermitte, Pillon, and Serdaru, 1986). The visual grasp reflex may also reflect the stimulus-bound behavior of patients with frontal lesions. Guitton, Buchtel, and Douglas (1985) found that lesions anywhere in the frontal cortex caused difficulty in making a directed saccade in the direction away from a visual cue (an anti-saccade), due to both a difficulty in suppressing a reflexive saccade to the cue and to slowed

initiation of a volitional saccade to the target. In short, patients with frontal lesions appeared excessively constrained by environmental cues.

Impairments in planning Patients with prefrontal cortex lesions have also been described as having little concern for either the past or for the future, lacking insight and foresight, as incapable of planning for the near or distant future, and as deficient in creativity (Ackerly and Benton, 1948; Eslinger and Damasio, 1985; Goldstein, 1944; Hebb and Penfield, 1940; Damasio, 1985). This set of abnormal behaviors may be a consequence of a deficit in the ability to simulate alternatives. In particular, patients with damage to the ventromedial portion of the prefrontal cortex appear to be insensitive to the future consequences of their actions and are excessively influenced by immediate reward (Bechara et al., 1994). Such deficits may occur because these patients have a diminished ability to simulate a future reality, including the consequences of a continued course of action; alternatively, they may simulate the outcome but be unable to attach an appropriate affective valence to it.

Deficits in estimation and frequency judgments Patients with frontal lesions are impaired at estimation. Smith and Milner (1984) showed that patients with focal frontal lesions performed poorly at a task involving estimating the price of common objects, with patients with right frontal lesions producing the greatest number of extreme errors. Shallice and Evans (1978) had frontal patients estimate the size of well known objects for which no ready size information was available, e.g., the length of the average man's spine. Frontal patients were seriously impaired at this task, at times giving wildly inaccurate and even impossible answers. To perform estimation tasks, subjects must recruit appropriate exemplars, construct category norms, and then select an appropriate size or price judgment. These processes all involve off-line simulation processes.

Temporal coding abnormalities Many empirical studies support specific impairments in the temporal coding of information, consistent with expectations from the animal literature. Patients with frontal lobe lesions are impaired in tasks involving temporal ordering, such as the sequencing of recent or remote events (McAndrews and Milner, 1991; Milner, Petrides, and Smith, 1985; Moscovich, 1989; Shimamura, Janowsky, and Squire, 1990), and temporal perception (Harrington, Halland, and Knight, 1998). In addition, these patients are impaired in making recency judgments (Janowsky, Shimamura, and Squire, 1989a,b; Milner, 1971; Milner, Petrides, and Smith, 1985; Janowsky et al., 1989), a process that prob-

ably relies on the correct temporal coding of events. Self-ordered pointing, a task in which the patient must remember the order in which objects have been indicated, is also impaired in patients with frontal lesions (Petrides and Milner, 1982). Temporal coding deficits are also influential in errors in planning and perhaps in extracting rules and developing heuristics to guide behavior. Planning may be defective in part because components of a plan are incorrectly ordered in time, and plans may terminate before end goals are reached (Sirigu et al., 1995). In a task involving the extraction of implicit rules, patients with lesions to the prefrontal cortex were impaired relative to controls with posterior lesions (Burgess and Shallice, 1996). Performance in this task is likely to be influenced by temporal coding errors. If a patient cannot confidently order both consequences and antecedents in time, forming an accurate representation of the reward and punishment structure of a task will be difficult, and this failure may lead to seemingly random and bizarre responses.

REALITY CHECKING

Overview The term "reality checking" refers to those aspects of monitoring the external world that have been called "reality *testing*" when they concern the present, and "reality *monitoring*" when they concern the past. Reality checking entails maintaining an awareness of the difference between an internally generated alternative reality and a current objective reality. This includes creating a representation of the context and modality of encoded information, termed source monitoring, and is consequently important for the construction of a detailed representation of an experience. Reality checking is essential for simulation processes to be carried out without compromising the ability to respond to the objective environment. Simulation processes generate an alternative reality that must be evaluated in relation to its divergence from the current reality. Depending on the affective valence of the counterfactual alternative, a plan may be created to change the current reality either toward or away from that alternative. Without the ability to maintain an up-to-date model of external reality, this process will fail. Likewise, if the internally generated reality is confused with the internal representation of the external reality, the process will also fail.

Reality monitoring Memories are created for events experienced in the world and for events experienced through internally constructed simulations. Given that both internal and external events create memory representations, what cues differentiate our internal models of

reality from our internal simulations of reality? Johnson and Raye (1981) studied subjects' abilities to discriminate between memories of external events and of internal events. Rich memory traces with many sensory features were ascribed to external experience. Memories of external events tend to be more detailed and have more spatial and temporal contextual information. Internally generated memories tend to be abstract and schematic, lacking in detail, but may include richer information about the cognitive operations involved in their construction. The two types of memory representations form overlapping populations, such that internal and external events may become confused. Reality checking involves a continual assessment of the relationship between behavior and the environment. The detection of novelty is essential to this process in order to incorporate changes in the environment into a representation of the external world. As an individual acts on the environment, the consequences of the action must be incorporated into existing plans.

Frontal lobe impairments and reality monitoring in schizophrenia Schizophrenic patients performed similarly to frontal lobe patients on a visuospatial working memory task and on planning in the Tower of London task, and performed worse on a measure of visuospatial memory span. Patients were also similar to controls with Parkinson's disease in terms of slower execution time subsequent to initiating the task, suggesting that both showed evidence of the cognitive slowing characteristic of basal ganglia disorders (Pantelis et al., 1997). These memory deficits suggest that schizophrenic patients, like patients with frontal lobe damage, may have difficulty in appropriately tagging events in time, and in protecting the ensuing representations from interference. Consequences of this failure may include both planning deficits and failures in reality monitoring. In fact, in a source memory task, both hallucinating and nonhallucinating psychiatric patients showed increased source attribution errors relative to controls after a delay of one week (Bentall, Baker, and Havers, 1991). Source attribution errors increased more for responses that were strongly associated with a cue than for those that were weakly associated. In addition, hallucinating psychotic patients were more likely to incorrectly attribute self-generated, low-probability (i.e., cognitively demanding) responses to the experimenter than were either nonhallucinating patients or normal controls, even though the hallucinating patients made an equivalent number of source attribution errors to the nonhallucinating patient controls. In another experiment, schizophrenic patients showed an increase in false alarms to new items relative to controls, misattributing them as having previously occurred when

they had not. In addition, they were also less accurate at making self-generated vs. other-generated decisions, with a bias toward attributing prior occurrences to an external source (Brebion et al., 1997). Thus, schizophrenic patients show clear evidence of impaired reality monitoring, which may be a consequence of frontal lobe dysfunction in their disease.

Source memory and confabulation Patients with damage to prefrontal cortex show a disproportionate impairment in memory for the source of information (Janowsky, Shimamura, and Squire, 1989b; Schacter, Harbluk, and McLachlan, 1984; Shimamura and Squire, 1987; Shimamura, 1995) and a higher false recognition rate (Schacter et al., 1996). Factual information may be correctly recalled but the spatiotemporal context in which the information was acquired is forgotten. These patients also have a diminished ability to make metamemory judgments (Janowsky, Shimamura, and Squire, 1989b). Metamemory includes an ability to judge whether or not the answer to a factual question has been or will be correctly retrieved. Patients with frontal lesions were impaired at making these judgments even though their memory for the facts was intact.

An interesting subgroup of amnesics are those who confabulate. Not all amnesics confabulate, but those who do are likely to have damage to the prefrontal cortex (Mayes, 1988; Moscovich, 1989). For patients who confabulate, plausible memories are not discriminated from implausible ones. This may reflect a reality monitoring deficit. In combination with a deficit in the temporal coding of events, these impaired processes lead to the selection of an alternative from among many others retrieved in a memory search, but this choice is made with little confidence and consequently many errors. Confabulation does not correlate with degree of memory impairment, but is correlated with the ability to self-correct (Stuss and Benson, 1986).

Reality monitoring and development of the frontal lobe Tertiary association areas including the prefrontal cortex are the last regions of cortex to complete development, with morphological development complete by adolescence (Orzhekhovskaya, 1981). Electrophysiological maturity of the brain starts in posterior regions and continues in a posterior-anterior direction (Hudspeth, 1985), with an increase in EEG coherence between frontal and posterior regions occurring during the period between 4 and 9 years of age (Thatcher, 1992). The prefrontal cortex is among the last regions to myelinate (Yakolev, 1962). Even within prefrontal cortex, developments occur at differing rates, with orbitofrontal cortex develop-

ing prior to the dorsolateral cortex. Full development of all aspects of the frontal cortex probably takes until about age 16, and changes continue well into adulthood, possibly allowing new cognitive skills to be continually added. In addition to the development of the frontal cortex, connectivity and interactions among the tertiary association areas may be essential for the development of higher cognitive operations such as simulation and reality checking.

There is evidence that children younger than 6 may perform like frontal patients on tests sensitive to frontal damage (Chelune and Baer, 1986; Schacter, Kagan, and Leichtman, 1995). Six-, seven-, and eight-year olds differed from adults in the number of categories achieved, the number of perseverative errors, and failures to maintain set. However, by age 9 children achieved adult levels in the number of categories achieved, and by age 10 children performed within the normal adult range on all measures. Further, children's test performance covaried with measures of their intellectual achievement. Of all the groups of children, the performance of 6-year olds was most similar to that of adults with focal frontal lesions. Children younger than 5 are also poor, relative to the performance of older children, at spatial memory span tasks, visual working memory tasks, and planning tasks (Luciana and Nelson, 1998).

The simulation and reality checking processes we have discussed are also fairly late to develop in children. Young children are poor at simulating another individual's point of view, including understanding that another person may hold a false belief. The ability to represent another person's belief correlates with performance on a working-memory task in children (Gordon and Olson, 1998) and with performance on a test of creativity (in 3- to 4-year olds; Suddendorf and Fletcher-Flinn, 1997). In another study, young children had difficulty with both a false belief task and with a task involving generating counterfactuals based on a change in some state of the world. This suggests the possibility that both tasks may depend on an ability to generate counterfactual alternatives (Riggs et al., 1998). Children aged 6 and younger also have difficulties with reality monitoring tasks. A group of 6-year olds performed poorly relative to 9- and 12-year olds in discriminating performed events from events that were watched or imagined (Markham, 1991). In a different task, 4-year olds who created a collage with an adult incorrectly remembered who placed which pieces, and misattributed the adult's actions as their own (Foley, Ratner, and Pasalacqua, 1993).

It is tempting to speculate that the development of these processes may follow the time course of maturation

of the prefrontal cortex. Of course, we cannot assume that similarity in the behavior of young children and of patients with focal frontal lesions arises from the same source; however, evidence that the behavior of humans with immature frontal lobes is similar to that of patients with frontal lesions provides converging evidence on the role of the frontal lobes in guiding complex behavior.

Conclusions

The extensive anatomical connections of prefrontal cortex led Nauta to propose that this region was involved in generating and evaluating internal models of action (Nauta, 1971). We propose that prefrontal cortex is crucial for detecting changes in both the internal and external environment and for discriminating internally and externally derived models of the world (Knight and Grabowecy, 1995). Extensive behavioral and physiological data have confirmed that prefrontal contributions are necessary for controlling neural activity in distributed neural networks. This flexibility of processing enables rapid and fluid mental movement through time as one's representation of the world is continually updated. Effortless movement through time occupies a major portion of conscious awareness and is linked to the massive evolution of human prefrontal cortex.

Many aspects of conscious awareness are altered in patients with prefrontal damage. Awareness of flow and change in the stream of internal and external events is impaired by deficits in novelty detection. Failures in inhibitory and excitatory regulation of neural networks critical for working memory contribute to impaired reality monitoring and impaired decision confidence. Inability to bridge temporal gaps and temporally sequence internal events alters coherent representations of counterfactual realities. Prefrontal damage does not eliminate the experience of consciousness, but it can ensnare the patient in a noisy and constrained present. Prefrontal patients suffer deficits in an ability that is a quintessential part of human experience—one we rarely appreciate since it is so effortless—the ability to escape from linear time.

93 Consciousness: Its Vicissitudes in Waking and Sleep

J. ALLAN HOBSON, EDWARD F. PACE-SCHOTT, AND ROBERT STICKGOLD

ABSTRACT Phenomenological, electrophysiological, and neuroimaging data show isomorphic differences between waking, non-REM (NREM), and REM consciousness states. Phenomenological data suggest that NREM sleep mentation is characterized by quantitative paucity and qualitative impoverishment in comparison to waking and REM sleep mentation. In comparison to waking mentation, REM sleep dreaming is characterized by motor and affective enhancement together with prominent executive deficits such as disorientation and amnesia. Electrophysiological data suggest that deepening NREM is characterized by the release of intrinsic thalamocortical rhythms such as spindle and delta waves as well as the onset of slower (<1 Hz) rhythms. By contrast, gamma-frequency (30–70 Hz) oscillations are ubiquitous in waking and REM sleep. Neuroimaging data indicate widespread deactivation of ascending arousal systems, subcortex, and cortex, with the transition from waking to NREM followed by preferential reactivation, in REM sleep, of the brainstem, diencephalic structures, striatum, limbic and paralimbic structures, and specific areas of association cortex but continuing deactivation of executive prefrontal structures and striate cortex. Dream changes in brain lesion patients largely complement neuroimaging findings, allowing construction of a preliminary integrated neuroanatomical model of brain regions involved in dreaming.

Few doubt that consciousness is a brain function. And there is now a great resurgence of interest in exactly how that function can be explained in terms of specific brain mechanisms. In this chapter, we review recent data on sleep and dreaming and attempt to integrate them with our previously published conceptualizations of the state-dependent aspects of consciousness. We begin with a brief review of recent findings on the phenomenology, electrophysiology, and neuroimaging of non-REM (NREM) sleep, but devote the bulk of our discussion to recent electrophysiological and neuroimaging studies of REM sleep and their integration with dream phenomenology and recent findings in dream neuropsychology. We conclude with an integrative model of the neuronal bases of REM sleep dreaming and a discussion of the biological bases for the cognitive differentiation between waking, NREM sleep, and REM sleep.

J. ALLAN HOBSON, EDWARD F. PACE-SCHOTT, and ROBERT STICKGOLD Laboratory of Neurophysiology, Department of Psychiatry, Harvard Medical School, Boston, Mass.

NREM sleep and the decline in level of consciousness

Neuroimaging (table 93.1) and electrophysiological studies strongly support a distinction between REM and NREM sleep as states whose differing activation patterns predict their observed psychological differences. The emerging picture is one of widespread cerebral deactivation during NREM, as compared to both waking and REM. Figure 93.1 illustrates this cycle of activation and deactivation in terms of its well-known behavioral and polysomnographic signs.

PHENOMENOLOGY OF NREM SLEEP MENTATION

Substantial recall of mentation from NREM sleep negates an exclusive association of sleep mentation with REM (e.g., Cavallero et al., 1992; Foulkes, 1967; Herman, Ellman, and Roffwarg, 1978). Nevertheless, early dream studies found that REM reports were more frequent (e.g., Goodenough et al., 1965), longer (e.g., Antrobus, 1983), more bizarre (e.g., Ogilvie et al., 1982), more visual (e.g., Goodenough et al., 1965), more often containing movement (e.g., Foulkes, 1962), and more emotional (e.g., Rechtschaffen, Verdone, and Wheaton, 1963) than NREM reports. New findings confirm a quantitative and qualitative distinction between REM and NREM sleep mentation even when reports are normalized for length (Casagrande et al., 1996; Waterman Elton, and Kenemans, 1993).

PET IMAGING STUDIES OF NREM SLEEP (SEE TABLE 93.1)

Relative to waking and REM, positron emission tomography (PET) studies of NREM sleep show a decrease in global cerebral energy metabolism (e.g., Maquet et al., 1997), global cerebral blood flow (e.g., Braun et al., 1997), and blood flow velocity (e.g., Kuboyama et al., 1997) of which at least energy metabolism decreases progressively with greater depth of NREM sleep (Maquet, 1995). In contrast, global cerebral energy metabolism in REM tends to be equal to (e.g., Braun et al., 1997) or greater than (e.g., Buchsbaum et al., 1989) that of waking. Regional declines in thalamic glucose or oxygen utilization relative to waking occur in NREM (Buchsbaum et al.,

FIGURE 93.1 Behavioral states in humans. States of waking, NREM sleep, and REM sleep have behavioral, polygraphic, and psychological manifestations. In the behavior channel, posture shifts (detectable by time-lapse photography or video) can occur during waking and in concert with phase changes of the sleep cycle. Two different mechanisms account for sleep immobility: disfacilitation (during stages I–IV of NREM sleep) and inhibition (during REM sleep). In dreams, we imagine that we move but we do not. The sequence of these stages is

represented in the polygraph channel. Sample tracings of three variables used to distinguish state are also shown: Electromyogram (EMG), which is highest in waking, intermediate in NREM sleep, and lowest in REM sleep; and electroencephalogram (EEG) and electrooculogram (EOG), which are both activated in waking and REM sleep and inactivated in NREM sleep. Each sample record is 20 s. Three lower channels describe other subjective and objective state variables. (From Hobson and Steriade, 1986.)

1989; Maquet et al., 1990, 1992, 1997; Braun et al., 1997; Hofle et al., 1997), and this decline is correlated with increased delta EEG activity (Hofle et al., 1997). Regional deactivation during NREM is also seen in the pontine brain stem, orbitofrontal cortex, and anterior cingulate cortex (Braun et al., 1997; Hofle et al., 1997; Maquet et al., 1997).

NREM SLEEP AND SLOW EEG OSCILLATIONS The decline in cerebral activation during NREM sleep probably reflects the progressive deactivation of the reticular activating system (RAS) which accompanies deepening NREM sleep and results in disfacilitation of thalamocortical relay neurons (Hofle et al., 1997; Maquet et al., 1997). This disfacilitation, in turn, allows the emergence of underlying thalamocortical oscillatory rhythms (Steriade, Contreras, and Amzica, 1994; Steriade, McCormick, and Sejnowski, 1993) such as spindle (12–14 Hz) and delta (1–4 Hz) frequency oscillations (Steriade et al., 1993; Steriade, Nunez, and Amzica, 1993a,b). The cortex may further entrain the spindle and delta-wave-generating thalamocortical bursts, as well as the K-complex, within a newly described slow (<1 Hz) oscillation seen in the cat

(Amzica and Steriade, 1998; Steriade, Nunez, and Amzica, 1993b; Contreras and Steriade, 1997; Marino, Martinez, and Canedo, 1996; Steriade, 1997). In humans, such slow oscillations include a novel 0.7 to 0.8 Hz rhythm as well as a periodicity in the grouping of spindle and delta-wave activity (Achermann and Borbely, 1997). In this deactivated state, intrinsic thalamocortical slow oscillations may be incompatible with the integrative demands of conscious experience that appear to be dependent upon much higher frequency synchronizing processes.

REM sleep and dreaming

If the cerebral machinery supporting consciousness is turned down in NREM sleep, how is it turned back up again in REM sleep so that dreaming is enhanced? And in what way does the REM sleep activation process differ from that of waking so as to account for heightened vividness and emotion and for the impaired critical thinking and memory of dreaming?

PHENOMENOLOGY OF REM SLEEP DREAMING REM sleep dreams have several distinctive formal features

TABLE 93.2
*The formal features of REM sleep dreaming**

<i>Hallucinations:</i>	Especially visual and motoric hallucinations, but occasionally in any and all sensory modalities
<i>Bizarreness:</i>	Incongruity (imagery is strange, unusual or impossible); discontinuity (imagery and plot can change, appear or disappear rapidly); uncertainty (persons, places, and events often bizarrely uncertain by waking standards)
<i>Delusion:</i>	We are consistently duped into believing that we are awake (unless we cultivate lucidity)
<i>Self-reflection:</i>	Absent or greatly reduced relative to waking
<i>Lack of orientational stability:</i>	Persons, times, and places are fused, plastic, incongruous, and discontinuous
<i>Narrative:</i>	Story lines explain and integrate all the dream elements in a confabulatory manner
<i>Emotions:</i>	Increased, intensified, and dominated by fear/anxiety
<i>Instinctual programs:</i>	Often incorporated—especially fight-or-flight
<i>Volition:</i>	Volitional control greatly attenuated
<i>Memory:</i>	Memory deficits across dream-wake, wake-dream, and dream-dream transitions

*Extensive references documenting each of the above features can be found in Hobson, Stickgold, and Pace-Schott (1998).

that the underlying brain state must somehow determine. These include sensorimotor hallucinations, bizarre imagery and events, the delusional belief that one is awake, diminished self-reflective awareness, orientational instability, narrative structure, intensification of emotion, instinctual behaviors, attenuated volition, and very poor memory. Table 93.2 summarizes these features (see Hobson, Pace-Schott, and Stickgold, 1998). Our discussion is based upon our psychophysiological theory of brain–mind isomorphism, as first specified in the activation-synthesis hypothesis of dreaming (Hobson and McCarley, 1977) and more recently elaborated in the AIM model of conscious state determination (Hobson 1997a; Hobson and Stickgold, 1995; Kahn, Pace-Schott, and Hobson, 1997).

We assume that any enhancement (or impairment) of any psychological function (e.g., dreaming) will be mirrored by enhancement (or impairment) of its physiological substrate's function (e.g., REM sleep). We have emphasized these formal aspects of dreaming because they are noted in all REM sleep dreams regardless of their specific narrative content. We expect that REM sleep neurobiology will be able to explain more about such generic formal features than it now can about specific dream content.

GAMMA-FREQUENCY (30–70 Hz) OSCILLATIONS IN WAKING AND REM Studies on gamma-frequency oscillations reinforce the distinction between REM and NREM as well as the similarities between REM and waking that have been described in neurophysiological models of sleep-cycle control such as the reciprocal interaction hypothesis (figure 93.2). Such gamma-range oscillations have been widely interpreted to reflect cognitive processing both while awake or in REM during dreaming (Hari and Salmelin, 1997; Kahn, Pace-Schott,

and Hobson, 1997; Llinas and Ribary, 1993; Llinas et al., 1994; Steriade, 1996). Although gamma-frequency oscillations have recently been reported during slow-wave sleep in cats, these oscillations are strongly suppressed during the hyperpolarization phase of each slow wave (Steriade and Amzica, 1996; Steriade, Amzica, and Contreras, 1996).

In animal models, gamma-frequency oscillations become strongly synchronized following arousal, focused attention, or a salient external or internal stimulus (Amzica and Steriade, 1996; Gray and McCormick, 1996; Kreiter and Singer, 1996; Munk et al., 1996; Steriade and Amzica, 1996; Steriade et al., 1996). In extracellular recordings in the cat, PGO waves appear synchronously at multiple cortical sites and become increasingly synchronized over the course of a REM period (Amzica and Steriade, 1996). This finding highlights the important fact that endogenous, REM-related stimuli are effective in evoking the same synchronization of gamma oscillation as exogenous sensory stimuli (Amzica and Steriade, 1996).

In humans, EEG studies have shown gamma-frequency oscillations to be associated with visual stimuli (Lutzenberger et al., 1995; Muller et al., 1996; Tallon-Baudry et al., 1996) as well as with specific functions of working memory (Tallon-Baudry et al., 1997, 1998). Moreover, gamma-frequency oscillations have been observed to bear distinct relationships with hippocampal theta rhythms, suggesting an important role in learning and memory phenomena (Chrobak and Buzsaki, 1998).

With respect to the question of how the brain is reactivated in REM so that the off-line consciousness of dreaming is possible, the answer appears to be that the reticular neurons of the pontine tegmentum are activated, presumably via the same aminergic disinhibition found in cats. The pons activates the midbrain and, in turn, the

A. Structural Model

B. Dynamic Model

C. Activation Level

thalamocortical system, such that its spontaneous slow oscillations are arrested and consciousness is reinstated. The cortical desynchronization seen in the surface EEG reflects this central core activation as does the high-frequency (30–70 Hz) gamma activity which, unlike slow oscillations, tends toward stimulus-evoked synchronization with greater activation (Munk et al., 1996; Steriade, 1996; Steriade and Amzica, 1996; Steriade, Amzica, and Contreras, 1996; Steriade et al., 1996). It is in these ways that the thalamocortical brain is similar in waking and REM sleep. Now, what about the differences?

PET IMAGING STUDIES OF REM SLEEP Recent PET imaging studies of REM sleep reveal many of the physiological differences underlying phenomenological differences between REM sleep dreaming and NREM and waking mentation. These findings, which are summarized in table 93.1, provide important new data for our understanding of dream synthesis by the forebrain, as summarized at the end of this section and in figure 93.4.

Compared to waking, the new imaging studies indicate a preferential activation of limbic and paralimbic regions of the forebrain in REM sleep (Braun et al., 1997; Maquet et al., 1996; Nofzinger et al., 1997) and, simultaneously, significant deactivation of the dorsolateral prefrontal cortex (Braun et al., 1997; Maquet et al., 1996). Two of these studies validate experimental animal data on the critical and specific role of the pontine brain stem

FIGURE 93.2 The reciprocal interaction model of physiological mechanisms determining alterations in activation level. (A) Structural model of reciprocal interaction with synaptic modifications of the original model (McCarley and Hobson, 1975) based upon recent findings of self-inhibitory cholinergic autoreceptors in mesopontine cholinergic nuclei and excitatory interactions between mesopontine cholinergic and noncholinergic neurons. In the original model, REM-on cells of the pontine reticular formation are cholinergically excited and/or cholinergically excitatory (ACH+) at their synaptic endings (open circles) while pontine REM-off cells are noradrenergically (NE) or serotonergically (5HT) inhibitory (–) at their synapses (filled circles). Note that the exponential magnification of cholinergic output predicted by the original model can also occur in this model, with mutually excitatory cholinergic–noncholinergic interactions taking the place of the previously postulated, mutually excitatory cholinergic–cholinergic interactions. In the revised model, inhibitory cholinergic autoreceptors would contribute to the inhibition of LDT and PPT cholinergic neurons, which is also caused by noradrenergic and serotonergic inputs to these nuclei. Therefore, the originally proposed shape of reciprocal interaction's dynamic model and its resultant alternation of behavioral state also result from this revised model. (See Hobson, Pace-Schott, and Stickgold, 1998, for more details and references.) (B) Dynamic model. During waking, the pontine aminergic (dashed line) system is tonically activated and inhibits the pontine cholinergic (solid line) system. During NREM sleep, aminergic inhibition gradually wanes and cholinergic excitation reciprocally waxes. At REM sleep onset, aminergic inhibition is shut off and cholinergic excitation reaches its high point. (C) Activation level. As a consequence of the interplay of the neuronal systems shown in A and B, the net activation level of the brain is at equally high levels in waking and REM sleep and at about half this peak level in NREM sleep. Symbols and abbreviations: Open circles, excitatory postsynaptic potentials; closed circles, inhibitory postsynaptic potentials; RN, dorsal raphe nucleus; LC, locus coeruleus; mPRF, medial pontine reticular formation; PPT, pedunculopontine tegmental nucleus; LDT, laterodorsal tegmental nucleus; 5HT, serotonin; NE, norepinephrine; Ach, acetylcholine; glut, glutamate.

in REM sleep generation (Braun et al., 1997; Maquet et al., 1996). Moreover, instead of the global, regionally nonspecific picture of forebrain activation that had been suggested by older EEG studies, all of these new imaging studies indicate a preferential activation of limbic and paralimbic regions of the forebrain in REM sleep compared to waking or to NREM sleep (Braun et al., 1997; Maquet et al., 1996; Nofzinger et al., 1997).

Maquet and colleagues (1996) used an $H_2^{15}O$ positron source to compare REM sleep activation to other behavioral states in subjects who were subsequently awakened for the solicitation of dream reports. In addition to the pontine tegmentum, significant activation was seen in both amygdalae and in the anterior cingulate cortex (table 93.1). These authors also noted REM-associated deactivation of a vast area of the dorsolateral prefrontal cortex (table 93.1).

FIGURE 93.3 Convergent findings on relative regional brain activation and deactivation in REM compared to waking. A schematic sagittal view of the human brain shows those areas of relative activation and deactivation in REM sleep compared to waking and/or NREM sleep which were reported in two or more of three recent PET studies (Braun et al., 1997; Maquet et al., 1996; Nofzinger et al., 1997). Only those areas that could be easily matched between two or more studies are illustrated

here and no realistic morphology of the depicted areas is implied. Note that considerably more extensive areas of activation and deactivation are reported in the individual studies; these more detailed findings are given in table 94.1. The areas depicted in this figure are thus most realistically viewed as representative portions of larger CNS areas subserving similar functions (e.g., limbic-related cortex, ascending activation pathways, and multimodal association cortex).

In another $H_2^{15}O$ PET study, Braun and colleagues (1997) replicated the Maquet group's findings of a consistent REM-related brainstem, limbic, and paralimbic activation. When REM sleep brain activity was compared to brain activity in delta NREM, pre-sleep waking, and post-sleep waking, the Braun group showed relative activation of the pons, the midbrain, the anterior hypothalamus, the hippocampus, the caudate, and the medial prefrontal, caudal orbital, anterior cingulate, parahippocampal, and inferior temporal cortices in REM sleep as compared to each of the above three conditions (table 93.1). These authors also noted a REM-associated decreased activation in dorsolateral prefrontal and parietal heteromodal association cortices (table 93.1). Braun and colleagues (1998) have recently expanded their findings to describe a unique pattern of striate cortex deactivation and extrastriate activation in REM sleep compared to waking as well as to NREM.

Using an ^{18}F -fluorodeoxyglucose (FDG) PET technique to compare REM sleep and waking, Nofzinger and colleagues (1997) confirmed the widespread limbic activation of the human brain in REM, showing increased glucose utilization in the lateral hypothalamic area, the amygdaloid complex, and a large "bilateral confluent paramedian zone which extends from the septal area into ventral striatum, infralimbic, prelimbic, orbitofrontal and anterior cingulate cortex" (p. 192). These authors, how-

ever, did not observe the REM-associated decrease in dorsolateral prefrontal activation, a discrepancy possibly due to the poorer temporal resolution of ^{18}FDG compared to $H_2^{15}O$ techniques (Bootzin et al., 1998).

Figure 93.3 illustrates regions relatively activated and deactivated in two or more of these three recent PET studies (Braun et al., 1997; Maquet et al., 1996; Nofzinger et al., 1997).

Additional neuroimaging studies support the findings of the Braun, Maquet, and Nofzinger groups. For example, the anterior cingulate cortex has consistently shown increased activation in REM in other PET studies (Hong et al., 1995; Bootzin et al., 1998). In addition, FDG PET activation of anterior medial structures, including the anterior cingulate and medial frontal cortex, was found to correlate with REM density in the REM period during which FDG uptake occurred (Hong et al., 1995). Finally, REM-associated decreases in cerebral blood flow to frontal areas during REM have also been noted using single photon emission computed tomography (SPECT) (Madsen et al., 1991).

Lesion studies and the neuropsychology of dreaming

An important complement to recent neuroimaging findings is provided by the clinical neuropsychology of changes in the subjective experience of dreaming—and

especially its formal properties—that are caused by localized brain lesions. Previous results of investigations using this method have provided tantalizing hypotheses of a critical disconnection in the left parieto-occipital region as the basis of cessation of dreaming following strokes (Doricchi and Violani, 1992; Greenberg and Farah, 1986), but these studies were limited by the small number of cases studied (e.g., Greenberg and Farah, 1986) or by the retrospective secondary nature of larger clinical series (Doricchi and Violani, 1992).

In a new study, Solms (1997) administered a 13-question dream interview to all patients referred to him over a four-year period to assess possible cerebral injury. Patients retrospectively compared pre- and post-illness dream features such as dream frequency, complexity, emotional valence, and visual imagery. Standard CT and MRI were used to localize lesions. Solms then statistically compared inventory responses with lesion locale. Based upon his findings and a review of 73 extant publications on the dreaming-related sequelae of cerebral injury, Solms proposes a new nosology for cerebral injury-related disorders of dreaming as well as a comprehensive model of the contributions and interactions of different brain regions in normal dreaming.

Solms has shown that two distinct syndromes comprise the classical Charcot-Wilbrand syndrome, which was previously defined as the cessation of dreaming, the inability to produce mental imagery in waking (visual irremembrance), prosopagnosia, and topographical agnosia or amnesia. In one syndrome, “global anoneria,” a global cessation of dreaming results from either posterior cortical or deep bilateral frontal lesions. In a second syndrome, “visual anoneria,” bilateral medial occipitotemporal lesions produce full or partial loss of dream visual imagery. Among his own patients (which, importantly, included 29 controls found to lack any cerebral illness), Solms reports a strikingly different incidence of the two proposed symptom complexes, with only two patients (1.1%) showing attenuated visual dream imagery while 34.9% showed a global cessation of dreaming.

Solms’s patients confirmed that either posterior cortical or deep medial frontal lesions produced global anoneria. The posterior global anoneria syndrome resulted from lesions of the inferior parietal lobes in either hemisphere, with lesions to Brodmann’s areas 39 and 40 being the most restricted damage sufficient to produce the syndrome. For the anterior variant of global anoneria resulting from deep medial frontal damage, bilateral damage to white matter in the vicinity of the frontal horns of the lateral ventricles was the most restricted site causing the syndrome.

Solms’s patients also supported the theory that bilateral medial occipitotemporal lesions produced visual anoneria in which dreaming continued to occur but in the absence of visual imagery. Notably, the cardinal waking correlate of visual anoneria was the classical Charcot-Wilbrand symptom of visual irremembrance. Solms also identified further variants of partial visual anoneria by the particular visual element affected (e.g., “kinematic anoneria” or “facial anoneria”).

In addition to disorders of attenuated dreaming, Solms reported another interrelated pair of symptom complexes that combined *increased* frequency and intensity of dreaming. He suggests that increased vivacity and frequency of dreaming is associated with anterior limbic lesions while recurring nightmares are associated with temporal seizures.

On the basis of these findings, Solms builds the following neuropsychological model of normal dreaming: Frontal dopaminergic mesolimbic reward circuits produce an instigating impetus for dreaming when activated by arousing stimuli (e.g., ascending brainstem arousal in REM). The passage of this subcortical stimulus to posterior heteromodal association areas in the inferior parietal lobe is gated by a reality-monitoring process in anterior limbic areas. These areas also interrupt voluntary motor signals and facilitate back projection processes. Back projection then continues from the inferior parietal lobe (which contributes the capacity for spatial cognition) to visual association areas in medial occipitotemporal cortex (which contribute visual imagery), but not as far back as primary visual cortex.

INTEGRATION OF IMAGING AND LESION FINDINGS The recent PET findings are important in several ways. First, they bring the neurobiology of human REM sleep into alignment with animal studies (via the brainstem activation). Second, they help to explain such positive cognitive dream features as the emotional intensification (via activation of subcortical and cortical limbic structures), the visuospatial vividness (via parietal operculum and unimodal visual association cortex activation), and fictive movement (via activation of basal ganglia, cerebellar vermis, and anterior cingulate). Third, they help to explain such negative cognitive dream features as the orientational instability, loss of self-reflective awareness, lack of directed thought, and amnesia (via the dorsolateral prefrontal deactivation). Each region showing REM-associated activation by neuroimaging has a counterpart effect in Solms’s lesion study of dreaming (table 93.3).

In most cases, lesions of areas activated in REM produce a global or partial deficit in dream experience. Particularly striking is the similarity between Solms’s findings that visual anoneria is caused by damage to vi-

TABLE 93.3

sual association but not primary visual cortex and PET findings by Braun and colleagues (1998) who found extrastriate activation but striate deactivation in the occipital lobes during REM sleep compared to waking.

Two exceptions to this general correspondence involve lesions of the brainstem (for which Solms reports no attenuation of dreaming) and lesions of the rostral limbic system (for which Solms reports an accentuation of dreaming). In the case of pontine lesions, based upon the difficulty of suppressing REM by experimental lesions of the pons in animals, we suggest that any lesion capable of destroying the pontine REM sleep generator mechanism would have to be so extensive as to eliminate consciousness altogether. In the case of the rostral limbic system, we speculate that there either could be irritative versus destructive lesions or that lesions in different areas of this functionally highly heterogeneous region (Devinsky, Morrell, and Vogt, 1995) could produce dramatically different effects.

An integrated model of REM sleep dreaming

Figure 93.4 presents a hypothetical model of normal dreaming that integrates findings from neuroimaging, neurophysiological, and lesion studies. In this model, dreaming consciousness results from processes of arousal impinging upon selectively facilitated, disfacilitated, or input/output-blockaded forebrain structures. The various elements of normal dreams are contributed by brain networks, which include structures known to contribute to analogous processes in waking—although, as the model suggests, dreaming is characterized by a deletion of certain circuits active in waking and, perhaps, the accentuation of others.

ASCENDING AROUSAL SYSTEMS (AREAS 1 AND 2 IN FIGURE 93.4) As in waking, activation of the forebrain oc-

curs through ascending arousal systems located in the brainstem reticular activating system (Steriade, 1996), the basal forebrain (Szyusiak, 1995), and possibly the hypothalamus (Saper, Sherin, and Elmquist, 1997), which together may form an integrated ascending midline network (Woolf, 1996). Forebrain stimulation by such arousal systems probably allows “consciousness” (as opposed to unconsciousness) to exist in dreaming and such consciousness may be detected by the desynchronization of the traditionally measured cortical EEG frequencies (Hobson, 1988) as well as by the appearance and synchronization of gamma-frequency oscillatory rhythms (Hobson et al., 1998; Kahn, Pace-Schott, and Hobson, 1997; Llinas and Ribary, 1993; Steriade, 1997).

THALAMOCORTICAL RELAY CENTERS AND THALAMIC SUBCORTICAL CIRCUITRY (AREA 6 IN FIGURE 93.4) During REM sleep, activated thalamic nuclei, which occupy key sites in relay and other brain circuits, probably contribute to most of the psychological modalities and phenomena of dreaming, while the release in the thalamus of intrinsic oscillatory corticothalamic circuits may suppress the experience of perception and mentation during NREM sleep (see above). Diverse roles of different thalamic nuclei may include transmission to the cortex of PGO-associated signals containing corollary discharge information on gaze shifts or activated motor patterns (Hobson and McCarley, 1977), modulation of the sleep cycle (Mancia and Marini, 1997), or participation in subcortical circuitry of motor pathways (Braun et al., 1997).

SUBCORTICAL AND CORTICAL LIMBIC AND PARALIMBIC STRUCTURES (AREA 3 IN FIGURE 93.4) Medial forebrain structures, especially limbic and paralimbic areas of the cortex and subcortex, appear to be selectively activated during REM sleep dreaming (Braun et al., 1997, 1998;

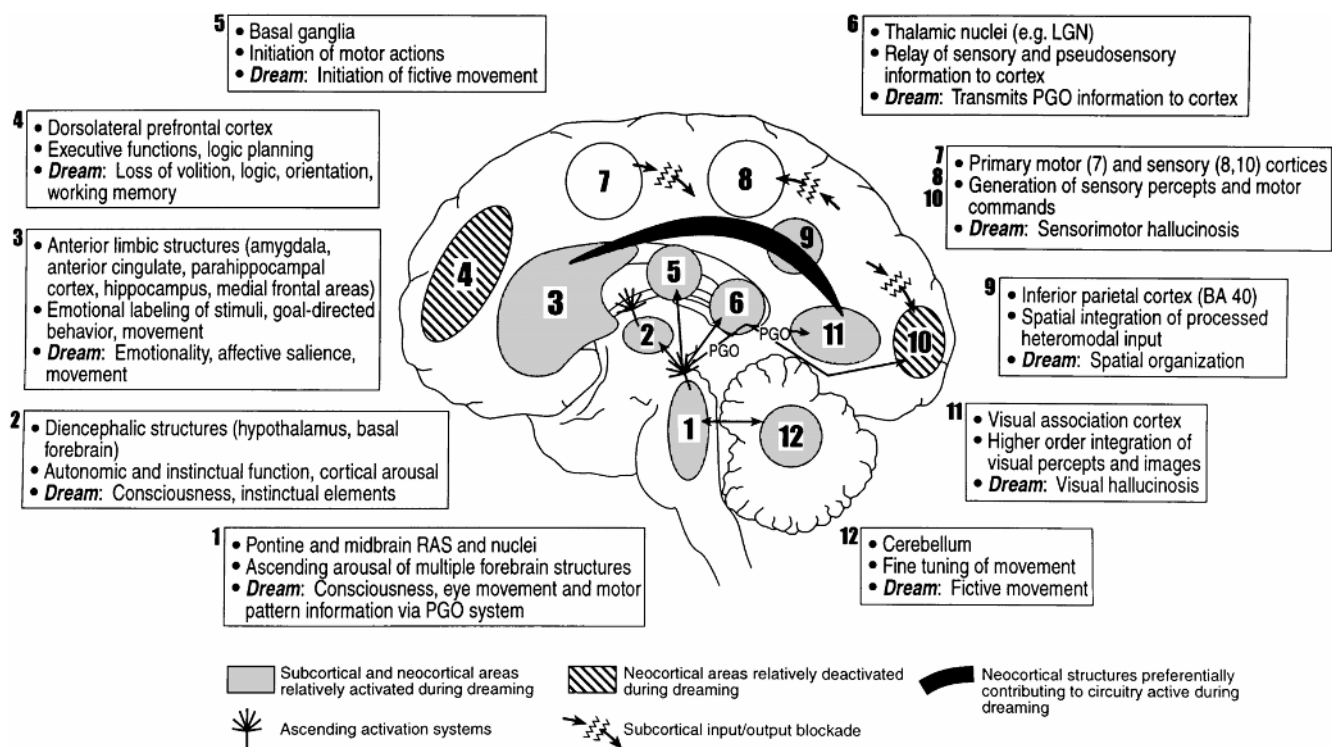

FIGURE 93.4 Forebrain processes in normal dreaming—an integration of neurophysiological, neuropsychological, and neuroimaging data.

Maquet et al., 1996; Nofzinger et al., 1997) and this activation may underlie dream emotionality (Braun et al., 1997; Hobson, Pace-Schott, and Stickgold, 1998; Maquet and Franck, 1997). Such activated limbic structures include the amygdala, which mediates anxiety (LeDoux, 1995), the most prevalent dream emotion (Domhoff, 1996; Merritt et al., 1994; Nielsen et al., 1991); the anterior cingulate, which mediates emotional valence biases, salience assessment, and integration with motor actions (Devinsky, Morrell, and Vogt, 1995); orbitofrontal, insular, and medial prefrontal cortices with abundant limbic connections (Braun et al., 1997), whose disruption may cause dream-like confabulatory syndromes (Braun et al., 1997; Solms, 1997); and the hippocampus, in which the amygdala may mediate storage of emotional memories (Cahill and McGaugh, 1998)—interactions which may underlie the oft-hypothesized role of REM and dreaming in processing emotional memories (Braun et al., 1997; Cartwright, 1990; Hobson, Pace-Schott, and Stickgold, 1998; Kramer, 1993; Maquet et al., 1996; Maquet and Franck, 1997; Nofzinger et al., 1997; Perlis and Nielsen, 1993).

MOTOR INITIATION AND CONTROL CENTERS (AREA 5 IN FIGURE 93.4) Strong activation of the basal ganglia (Braun et al., 1997) may initiate the ubiquitous fictive

motion of dreams (Hobson, 1988; Porte and Hobson, 1996), and the striatum is extensively connected to the pedunculo-pontine area (Inglis and Winn, 1995; Rye, 1997), which also regulates REM phenomena (Hobson, Pace-Schott, and Stickgold, 1998). As in waking, other areas may modulate motion. For example: Vestibular dream sensations (Hobson et al., 1997; Leslie and Ogilvie, 1997) may arise via cerebellar connectivity with brainstem vestibular nuclei; motor cortices (area 7 in figure 93.4) participate in dream movement, as evidenced by the expression of dreamed action in REM sleep behavior disorder (Schenck, Hurwitz, and Mahowald, 1993); and premotor areas of the anterior cingulate cortex (Devinsky, Morrell, and Vogt, 1995) may integrate dream movement and emotion.

VISUAL ASSOCIATION CORTEX (AREA 11 IN FIGURE 93.4) Areas of the medial occipital and temporal cortices involved in higher-order visual processing, as opposed to primary visual cortex (area 10 in figure 93.4), may generate the visual imagery of dreams (Braun et al., 1998; Solms, 1997). As in waking, specific areas of the visual association cortex may process specific visual features of dreaming. For example, the fusiform gyrus both mediates waking face recognition (Kanwisher, McDermott, and Chun, 1997; McCarthy et al., 1997) and is

selectively activated in REM (Braun et al., 1997, 1998; Nofzinger et al., 1997). *Activation* of visual association (e.g., Brodmann areas 37 and 19) and paralimbic cortices with the *deactivation* of primary visual and dorsolateral prefrontal cortices has led Braun and colleagues (1997, 1998) to suggest that REM constitutes a unique cortical condition of internal information processing (between extrastriate and limbic cortices) functionally isolated from input (via striate cortex) or output (via frontal cortex) to the external world.

INFERIOR PARIETAL LOBE (AREA 9 IN FIGURE 93.4) The inferior parietal lobe, especially Brodmann's area 40, may generate the perception of a fictive dream space necessary for the global experience of dreaming (Solms, 1997; see also Doricchi and Violani, 1992) while PET scans show its activation despite widespread parietal deactivation (Maquet et al., 1996). Moreover, both lesion and PET studies suggest a greater importance of the right versus the left inferior parietal lobe (Maquet et al., 1996; Solms, 1997).

DORSOLATERAL PREFRONTAL EXECUTIVE ASSOCIATION CORTEX (AREA 4 IN FIGURE 93.4) Deactivation of frontal executive areas such as the dorsolateral prefrontal cortex during NREM (Braun et al., 1997, 1998; Hofle et al., 1997; Maquet et al., 1997) followed by their failure to reactivate along with medial paralimbic areas in REM (Braun et al., 1997, 1998; Maquet et al., 1996) may underlie the prominent executive deficiencies of dream mentation (Hobson, Pace-Schott, and Stickgold, 1998; Kahn, Pace-Schott, and Hobson, 1997). For example, in waking, prefrontal cortical areas are selectively activated during reasoning (Goel et al., 1998), episodic memory (Fletcher, Frith and Rugg, 1997), and working memory (Goldman-Rakic, 1996). Prefrontal deactivation in dreaming may, therefore, lead to illogical reasoning such as ad hoc explanations (Williams et al., 1992), prominent mnemonic deficits (Pace-Schott, Stickgold, and Hobson, 1997), and bizarre uncertainties (Hobson et al., 1987). Interestingly, hypoperfusion of the frontal cortex has been associated with pathological temporal limbic activation in epilepsy (Rabinowicz et al., 1997) and reciprocal inhibition between frontal and limbic areas has been hypothesized in theories on the etiology of schizophrenia (Weinberger, 1995). Possibly REM sleep dreaming involves a normal physiological state of the brain analogous to psychopathological conditions (Hobson, 1994, 1997b) in which limbic hyperactivation is combined with frontal hypoactivation.

DYNAMIC INTERACTIONS OF BRAIN REGIONS DURING NORMAL DREAMING—HYPOTHESES Component subsystems of global states of consciousness (like memory

or visual processing) are physically instantiated in networks, each consisting of several to many discrete brain regions (e.g., see Cummings, 1993; Kolb and Whishaw, 1996; Nadel, 1994). At this early stage in dream neuropsychology research, a few generalizations are beginning to emerge. First, ascending arousal systems activate the many forebrain regions involved in dream construction but do so in a manner chemically and perhaps anatomically different from waking arousal processes. Second, cortical circuits activated in dreaming favor more medial circuits linking posterior association and paralimbic areas (represented by central crescent in figure 93.4) versus circuits including the primary sensory cortex and/or frontal executive regions (see Braun et al., 1998). Third, subcortical circuits involving the limbic structures, basal ganglia, diencephalon, and the brainstem contribute strongly to regional brain activation in REM and probably therefore also to the physiological substrate of dreaming.

Implications for changes in consciousness with changing behavioral state

DIFFERENCES BETWEEN NREM MENTATION AND WAKING Compared to waking, the deactivation of ascending arousal systems in the pons, midbrain, and diencephalon with the onset and progression of NREM sleep is likely to translate into a lower level of global forebrain activation (Braun et al., 1997; Hofle et al., 1997; Maquet et al., 1997) with a concomitant decrease in cognitive output from the cerebral cortex. In addition, the regional deactivation in NREM of multimodal association cortices in prefrontal and parietal areas compared to waking (Braun et al., 1997, 1998) might selectively constrain higher-level cognitive activity in NREM. As noted, gamma-frequency oscillations are continuous during REM and waking but, in NREM, are intermittent, being suppressed during the prolonged portions of slow waves corresponding to hyperpolarization (Steriade, 1997). Such periodic interference with those cortical rhythms associated with conscious processes may represent one example of a physiological isomorphism with the phenomenological observation that NREM mentation is more sporadic and limited than either REM or waking mentation.

DIFFERENCES BETWEEN REM AND NREM SLEEP MENTATION Previous publications have linked phenomenological differences between REM and NREM mentation in terms of neuromodulatory changes (e.g., Hobson, 1988, 1994, 1997a) as well as to patterns of neuronal oscillation (e.g., Kahn, Pace-Schott, and Hobson, 1997; Hobson et al., 1998). The current chapter adds striking

neuroimaging findings to these other measures on the physiological substrate of psychological differences between mentation in these two states. In summary, the regional pattern of deactivation in NREM sharply contrasts with the regional *activation* of these same regions (i.e., thalamus, pontine brainstem, anterior cingulate cortex) in REM (table 93.1). The level of consciousness falls in parallel with brain deactivation in NREM sleep, and we hypothesize that it is the thalamocortical deactivation allowing emergence of intrinsic slow thalamocortical rhythms that may cause the depression of conscious experience in NREM sleep. Moreover, compared to REM sleep, the decreased activation of limbic-related cortical structures such as the anterior cingulate in NREM (Braun et al., 1997; Hofle et al., 1997; Maquet et al., 1997) may limit the affectively biased thought characteristic of REM-sleep dreaming.

DIFFERENCES BETWEEN REM AND WAKING MENTATION Taken together, the imaging, brain lesion, and electrophysiological results strongly suggest that the forebrain activation and synthesis processes underlying dreaming are very different from those of waking. Not only is REM sleep chemically biased but the preferential cholinergic neuromodulation is associated with selective activation of the subcortical and cortical limbic structures (which mediate emotion) while the aminergic demodulation is associated with relative inactivation of the frontal cortex (which mediates directed thought). This wake-to-REM sleep shift from the top to the bottom and from the front to the back of the brain may correspond, in a crude but compelling way, to the shift from the deliberate, environmentally integrated character of waking consciousness to the automatic, internally directed character of dream consciousness.

ACKNOWLEDGMENTS This project was funded by the MacArthur Foundation Mind Body Network and NIH MH-48,832, MH13923 and MH01287. The authors wish to thank Dr. Eric A. Nofzinger, Dr. Allen R. Braun, Dr. David Kahn, Dr. James Quattrochi, Dr. Rosalia Silvestri, Jill Gustafson, Dorthea Abbott, and April Malia for their collaboration.

94 Consciousness, Introspection, and the Split-Brain: The Two Minds/One Body Problem

KATHLEEN BAYNES AND MICHAEL S. GAZZANIGA

ABSTRACT The history of split-brain research and its relation to our understanding of consciousness and modularity is reviewed briefly. Owing to the limited control of expressive language by the right hemisphere (RH), the problem of the level of consciousness in the RH is presented as approachable only through observation of behavioral changes that demonstrate its contribution to consciousness. The role of memory, emotion, and language in our understanding of conscious behavior in the RH is reviewed. Insight gained from data obtained from a new patient with anomalous language representation is presented. An evolutionary perspective is considered.

There are two mysteries regarding the sectioning of the corpus callosum. One emerges when the researcher observes the activity of two separate cognitive systems in one person, each acting out of the consciousness of the other. And the second emerges when the researcher observes the placid acceptance of this state by the split-brain patients themselves. Patients respond to requests for introspection with a curious lack of insight or interest. Don't we all believe that we would be dismayed by an apparent "other" inhabiting our brains? But perhaps not, depending upon how we understand the effect that sectioning of the corpus callosum has on the structure of our conscious selves.

The mystery of the status of consciousness in the split-brain may not be easily answered, as answering the question of the consciousness of the nondominant hemisphere is equivalent to defining consciousness itself. Neuroscience has made inroads into the concept of consciousness, reducing some of its aspects to empirically approachable chunks. What these chunks are depends in part on the perspective of the writer. Definitions of consciousness differ from the matter-of-fact assessment of the neurologist, eliciting an ability to respond and withdraw from pain, to the exquisite awareness of ourselves and our place in the world that troubles the

philosopher. Contemporary theories of consciousness frequently recognize two, or perhaps three, kinds of consciousness (Tulving, 1985; Pinker, 1997). And many question whether the most interesting aspects of consciousness are tractable problems at all (Dennett, 1991). Whatever the ultimate solution to the problem of consciousness, it seems likely that it will be multifaceted, perhaps breaking apart in ways we have not yet begun to think about.

We want to use the idea that our skulls may house very different states of consciousness under different circumstances to examine the possible states of consciousness in the right and left hemispheres. It was our subjective notion of a unity of consciousness that made the first observations of split-brain behavior so astounding. There is clearly a separation of cognitive function after section of the callosum. But some have argued that the impression of two consciousnesses is illusory (Eccles, 1965). Dennett (1991), for example, has suggested that the right hemisphere (RH) has, at best, a "rudimentary self." We, too, believe that the RH has more limited cognitive abilities than the left; but we feel it is crucial to accurately assess the upper extent of its cognitive function.

Here, we review the progress made in the study of dual consciousness in the split-brain subject with an emphasis on the relation to language processing. Consciousness is not likely to be an all-or-nothing concept. Consciousness has multiple facets, and we may see some of them displayed more clearly in the split-brain and other neurological populations. But they are ultimately combined to form the totality of our conscious experience. Language is one of these aspects—an aspect that has been important to the study of the split-brain patient. But we wish to maintain that it is not sufficient of itself.

The early years

The ground-breaking observation in the 1960s that section of the corpus callosum in humans yielded a being in whom some forms of information could be isolated to

KATHLEEN BAYNES Center for Neuroscience, University of California at Davis, Davis, Calif.

MICHAEL S. GAZZANIGA Director, Program in Cognitive Neuroscience, Dartmouth College, Hanover, N.H.

FIGURE 94.1 Cartoon of data collection from early split-brain studies. Words presented to the LVF/right hemisphere allowed the left hand to select the correct object by touch. (From Gazzaniga, 1983.)

one hemisphere and responded to only by that hemisphere was a remarkable one. In 1962 the surgical team led by Bogen and Vogel sectioned the callosum of a patient who, prior to surgery, could name stimuli presented in either visual field or placed in either hand (Gazzaniga, Bogen, and Sperry, 1962). After the surgery, he could not name items displayed in his left visual field or presented to his left hand (figure 94.1). However, when given a nonverbal method of response, the RH was indeed able to demonstrate knowledge to which the left hemisphere (LH) was not privy (Gazzaniga, Bogen, and Sperry, 1962, 1965).

These experiments and those that followed demonstrated that each hemisphere could have knowledge of things the other did not and could respond on the basis of this independent experience. Of the first six patients operated on, two patients, L.B. and N.G., showed language competence in their RHs (Gazzaniga and Sperry, 1967). Although the RH appeared helpless when spoken responses were required, allowing tactile or pointing responses permitted the RH to show it had a written and

auditory vocabulary with some level of “abstraction, generalization, and mental association” (ibid, p. 137). Further, this work confirmed that the LH in isolation could continue to carry out basic language functions, speaking, reading, and writing normally. The RH, too, appeared to be carrying out basic functions. Patients did not exhibit neglect of intrapersonal or extrapersonal space; they did not bump into objects in the left hemisphere or fail to orient or attend to visual or auditory information in the normal situation. So, despite the dramatic differences that could be seen in special experimental situations, these people appeared to be going about their normal daily lives without disruption and did not report changes in their conscious perception of the world.

Recent research

In the years that followed, researchers in the Gazzaniga laboratory have tried to characterize the nature of conscious mechanisms in these patients. Gazzaniga (1995) tracked the major findings in split-brain research as they relate to the larger questions of how our brains enable everyday reality, how we incorporate experience into that reality, and the role and nature of the self within that context. Insights into emotion, memory, and the role of the left hemisphere in interpreting our actions will be reviewed here briefly before focusing on the relation between linguistic skill and conscious experience in the right hemisphere.

EMOTIONAL INTELLIGENCE Our short list of some of the components of a conscious life suggests that emotional valence is one of them. The RH does not have easy access to verbalization, but can it experience emotions? Early work with patient P.S. indicated that his RH had some emotional reactions to stimuli and was able to maintain some goals and opinions that differed between his hemispheres (LeDoux, Wilson, and Gazzaniga, 1977a; Gazzaniga, LeDoux, and Wilson, 1977).

There also appears to be some specificity to the emotion that the RH can experience. In an experiment done with patient V.P. (see table 94.1), there appears to be sufficient specificity in the emotional arousal of the RH that the LH is able to correctly discern the emotion experienced although uninformed as to the real cause. In one instance a frightening scene of a fire was shown to V.P.’s RH. After viewing this scene, she said, “I don’t really know what I saw; I think just a white flash. Maybe some trees, red trees like in the fall. I don’t know why, but I feel kind of scared. I feel jumpy. I don’t like this room, or maybe it’s you guys getting me nervous” (Gazzaniga and LeDoux, 1987). In this case, the response to the

TABLE 94.1
Ages of onset, time of surgery, and callosal damage of patients discussed here

ID	Sex	Handedness	Age at Onset (Years)	Age at Surgery (Years)	Callosal Damage	Post-Event IQ

A.W.*	Female	Right	50	—	Vascular disease: Thinning of body of callosum	93 (WAIS-R)

*A.W. suffered anarchic or alien hand symptoms following a vascular lesion. There was no surgical intervention.

scene appears to have been physiological and specific enough that the LH identified it correctly. The cause was not known, so the immediate surroundings were seen as suddenly scary. In the context of this discussion, the point is that the RH saw a frightening scene and interpreted it correctly and specifically.

From another point of view, this experimental evidence illustrates an extreme case of a phenomenon that commonly occurs to all of us. A change in mood alters the physiological state of the brain. In response, the verbal system notes the mood and attributes cause to the feeling based on available evidence. Cognitive interpretations of physiological changes in normal subjects have been reported in experiments performed by social psychologists (i.e., Dutton and Aron, 1974). Those experiments were seen as evidence that all physiological responses are similar and that it is the cognitive interpretation that labels them as specific emotions. In the instance above, however, it appears the RH is capable of a specific emotional response to a simulated situation. The abstract visual presentation has a physiological result that the LH can recognize as fear. It may be that the LH interpreter is easily “tricked” by clever psychologists into re-interpreting a physiological response to fit the circumstances with which it is confronted; but in the case of V.P., the physiological response seems sufficiently specific to indicate that the RH was experiencing the emotion expected under the circumstances.

In the examples reviewed here, it appears that the RH not only makes an interpretive contribution to the world about which the LH speaks, but has a specific set of emotional reactions as well. One prediction from these results is that the isolated LH might be more easily “misled” about the emotional valence of a physiological response. For present purposes, however, it is the accurate emotional valence of the RH in response to a simulation that is relevant to evaluating its level of conscious behavior.

CALLOSOTOMY AND MEMORY It remains difficult to quantify the costs to cognitive ability incurred by callosal section. Early studies showed no change in reaction time for simple discriminations (Gazzaniga and Sperry, 1966), in the ability to form hypotheses (LeDoux, Wilson, and Gazzaniga, 1977b), or in verbal IQ (Campbell, Bogen, and Smith, 1981), suggesting no substantial contribution to psychometric intelligence from the RH. However, there are numerous reports that negative effects can be registered on memory function (Zaidel and Sperry, 1974; Phelps, Hirst, and Gazzaniga, 1991; Jha et al., 1997). There may be changes in cognitive functions that are not easily captured by standard psychometric means. One of these functions is memory.

There have been subjective reports from family members that patients may suffer some memory failures post-callosotomy (Gazzaniga and Sperry, 1967). Although psychometric results sometimes suggested a decline in memory function, it was unclear why this would occur. Phelps and Gazzaniga (1992) examined the role that the LH interpreter might play in memory. They showed two patients, V.P. and J.W., a sequence of pictures that made up vignettes of familiar activities when viewed in order. Later, the pictures were interspersed with distractors that were either consistent or inconsistent with the vignette. (If, for example, the vignette were about a man getting ready for work, a picture of him pouring coffee would be consistent, but a picture of him pouring lemonade would not.) The patients were then asked to accept pictures they had seen before and reject those they had not seen. Both the right and left hemispheres could accurately accept the pictures they had seen before; and both could reject, as things they had not seen, pictures that were inconsistent with the vignette. The hemispheric difference was seen in the pictures that were consistent with the vignette. The RH was able to reject such pictures more accurately than the LH. Rather than enhance memory, the

LH interpretive activity interfered with accurate recognition. The RH was better able to reflect accurately what it had seen before.

There is also reason to believe that encoding of simpler material may be less effective after callosotomy. Jha and colleagues (1997) compared J.W., V.P., and D.R. (table 94.1) with patients with hippocampal damage on a series of verbal and visual memory tasks (Kroll et al., 1996). The split-brain patients made a large number of false-positive responses to lures made of combinations of previously viewed features, suggesting a binding problem similar to that seen in patients with right hippocampal lesions. This result suggests that the RH is contributing to the normal encoding process via callosal fibers and that, when divided, the hemispheres cannot carry out this binding process at normal levels of accuracy.

These experiments suggest that memory performance may decline after callosotomy not because of a change in memory processes per se but because the right and left hemispheres may make unique contributions to a fully elaborated memory trace. Split patients can learn new material, but may not encode it as fully and hence may not have as many retrieval cues at their disposal as they did prior to surgery.

CEREBRAL DOMINANCE AND THE INTERPRETER The demonstration of hemispheric specialization was perhaps less surprising than the persistence of the LH in explaining actions that it did not generate. Even in the early patients, the tendency of the LH to speak up in situations in which it was not informed was observed (Gazzaniga and Hillyard, 1971; Gazzaniga, LeDoux and Wilson, 1977). In a now-classic demonstration, P.S. (table 94.1)—one of the subjects with very well developed RH language—was being tested with bilaterally presented pictures (figure 94.2). After watching his right and left hands make disparate choices from an array of pictures, without batting an eyelash, his LH accounted verbally for the behavior it witnessed by combining that observation with the knowledge of the only display it had seen. No “Why did I do that?” but instead an automatic assumption of responsibility for the complete action it had just observed. This propensity of the LH to provide a rationale for disparate behaviors has led Gazzaniga to dub it the Interpreter (Gazzaniga, 1985).

This behavior in split-brain patients contrasts with that observed in alien (anarchic) hand patients with partial callosal lesions. These patients are mystified and distressed by the unintended actions of their nondominant (and sometimes dominant) hands. One patient, A.W., with a lesion of the central portion of the corpus callosum had no significant paralysis or sensory loss, but was unable to drive her car because her right hand grabbed

FIGURE 94.2 Patient P.S. confabulates about his left hand's choices when presented with bilateral picture displays. The right hand selects a rooster to match the claw seen by the left hemisphere, but P.S. states that the shovel selected by the left hand was needed to clean out the chicken house. The left hemisphere Interpreter had no knowledge of the snow scene seen by the right hemisphere. (From Gazzaniga and LeDoux, 1978.)

the wheel away from her left (Baynes et al., 1997). She complained that at the supermarket, her left hand has snatched back money she had just paid to the cashier with her right hand. This patient is aware of and distressed by her independently functioning left hand. What makes the difference between these two types of responses to left-hand actions outside the control of the LH? Why does A.W. not simply confabulate that she thought she had given the cashier the wrong amount of money or changed her mind about the purchase? In her case, the Interpreter sees the actions of that hand as strange and separate from itself. Hence, instead of trying to explain and incorporate the behavior, it rejects the actions and the limb itself.

Why doesn't A.W. confabulate about her behavior? Perhaps A.W.'s less precise callosal lesion interferes with the neural coding of the motor commands in a way that makes them impenetrable to the LH. In contrast, P.S.'s LH may receive appropriate feedback via ipsilateral fibers regarding the execution of the motor

action to assume it has generated them. Bisiach, Luzzatti, and Perani (1979) in explaining neglect and denial have suggested that not only is function lost, but also *expectations* about function. A.W. may still have unfulfilled expectations about the behavior of her left hand that P.S. lacks.

It would appear that the LH confabulates only under specific conditions which may require failing to receive constraining information from the RH. If this is the case, it would provide support for the belief that the RH is not only conscious in the sense of aware but is capable of formulating some basic hypotheses regarding the relation of its actions to the world. It may be in some sense fact-checking for the LH (Gazzaniga, 1998).

The modular organization of the human brain is well-accepted. The functioning modules do have some kind of physical instantiation, but the precise nature of the neural networks that carry out those functions has not been specified. What is clear is that they operate largely outside the realm of awareness, and that they announce their computational products to various executive systems that result in behavior or cognitive states. It may be the level at which this processing breaks down in the examples above that determines whether the Interpreter is conscious that the behavior originates outside of its control or simply observes and incorporates it in its world view. We want to emphasize our belief that there are multiple executive systems that may have varying degrees of influence over behavior depending upon the situation. Managing and interpreting all of this constant and parallel activity is the role of the LH's interpreter module, but under normal conditions it is informed and constrained by the RH (Gazzaniga, 1998).

The language connection

Although we recognize that the acute awareness of our activities—our experience of the struggle to convey a complicated idea or the taste of cold water when we are thirsty—is an essential part of our humanity, we also recognize the problem of solipsism. How do we know that these experiences are shared with anyone else? Is your blue, my blue? Your tiramisu, my tiramisu? We can only be reassured by our observations of others. When you speak of blue, you point to the same color patch I do, with great reliability. In fact, even if you don't have a word for blue, you reliably demonstrate you can see it (Berlin and Kay, 1969; Heider, 1972). So when we think about whether or not the separated right and left hemisphere apprehends the world in a manner similar to the connected brain, we have the same lack of absolute assurance. Throughout the development of split-brain research, this problem is exacerbated by the silence of the

FIGURE 94.3 Percent correct on judgments of grammaticality in the right and left hemispheres of patients V.P. and J.W. Both subjects do well identifying grammatical sentences, but cannot use this information to guide sentence comprehension. (From Baynes and Gazzaniga, 1988.)

RH. It can seldom assure us that it thinks or feels without the language apparatus of the LH.

Moreover, there are marked differences among those RHs that possess some language (Baynes, 1990). P.S., one of the early patients in the Dartmouth series, displayed a sophisticated language system, with knowledge of subtle differences in meaning as well as an appreciation of some grammatical differences (Gazzaniga and LeDoux, 1978). P.S. was also one of the patients who proved to be able to generate speech from his RH. A similar profile was seen in V.P., who also demonstrated a good lexicon, some ability to identify aurally presented grammatical sentences but limited ability to use grammatical information to aid her sentence comprehension (figure 94.3), and early development of speech in her RH (Gazzaniga et al., 1984; Baynes and Gazzaniga, 1988). These are also the patients in whom some RH emotional valence has been documented. It remains unclear if the more well-developed language system contributes to the actual generation of the emotional valence or if it only makes it easier to observe.

In contrast, patient J.W. was for many years the prototype of the mute RH. Despite not producing spoken speech, J.W. displayed an excellent aural and visual

vocabulary and could do a variety of semantic and grammatical tasks (figure 94.3), although generally not as accurately as V.P., despite psychometrically higher intelligence (Gazzaniga et al., 1984; Baynes and Gazzaniga, 1988; Baynes and Eliassen, 1998). He is skilled in drawing and even with his nondominant hand was often able to demonstrate recognition of stimuli displayed to his RH with his drawings. J.W.'s RH is skilled at a variety of nonlanguage tasks and has demonstrated relatively good attention and memory as well. These characteristics have been present since J.W.'s surgery, but more recently he has developed the ability to generate spoken responses to stimuli presented in his LVF (Baynes et al., 1995; Gazzaniga et al., 1996). This skill developed at a time well beyond the period associated with recovery of function after a neurological insult. How this apparent functional recovery occurred remains unknown. It is possible that the good auditory lexicon possessed by J.W.'s RH was sufficient for this process to occur, whereas other splits with language skills below a certain threshold are unable to develop in this way. However, a change of this nature implies a RH that is an active participant in the world, not a mere automaton.

Another problem in evaluating the status of language in the RH is the speed required to read tachistoscopic materials. Visual words are available for, at most, 150 milliseconds. Even the most verbally talented patients were slower to respond to words displayed to the RH, so perhaps some of our apparently nonverbal RH's could read, but not at tachistoscopic speeds. This was the case with D.R. (Baynes, Tramo, and Gazzaniga, 1992). D.R. was one of the brightest patients to undergo this surgery. She had a BA in accounting and had worked and traveled extensively. She enjoyed reading for pleasure. It seemed likely that, post-surgery, she would have a literate RH. However, after her surgery she was unable to respond accurately to many verbal experiments. It became apparent that if pictures were lateralized and D.R. was given the opportunity to read free-field, she could pick out the word that matched the picture she had seen. Since only her RH had seen the picture, this indicated that her RH could read when given sufficient time. Nonetheless, although D.R. can read free-field well enough to perform adequately on standardized tests, she no longer reads for pleasure, suggesting some change in language function following callosotomy.

A striking example of a loss of specific function due to section of callosal fibers occurred in patient V.J. Prior to surgery, V.J. was an avid reader who enjoyed corresponding with the members of her far-flung family. Post-surgery, V.J. became agraphic; i.e., she was unable to write at will or to take dictation with either hand. Although she has, over time, regained the ability to write

her signature, she remains unable to write despite extensive therapy. Unlike D.R., V.J. remains an avid reader; but now, almost three years post-surgery, she cannot write notes or lists or write words to dictation or the names of palpated objects. However, when words were lateralized tachistoscopically and her hands placed out of view, she was able to read out loud words displayed to her LH although she remained unable to write them (figure 94.4). More remarkably, when words were displayed to her RH, she was able to write them although she could not report them out loud (Baynes et al., 1998). In this patient, the motor commands for written language were isolated in her RH and could not be called into play by her dominant LH. Moreover, when asked to write the name of a picture or an object she had palpated, V.J. proved unable to do so. This ability to write words displayed to the LVF with the left hand, but to fail to write the names of pictures displayed to the LVF, suggested a slavish RH copying system that did not understand written language. But when asked to indicate whether words and pictures matched, V.J. proved very adept. Moreover, she also showed semantic priming in a lexical decision task in her RH, a task usually interpreted to indicate the presence of an intact semantic network. Her good, even excellent, performance on tasks that implied the presence of semantic knowledge was at odds with her apparent inability to write the name of a lateralized picture. She remained unable to write names, even when the pictures were displayed free field and she had as much time to respond as she needed.

The surprising lack of communication and integration in this system suggested that the language representation in V.J.'s right hemisphere might be a set of independent modules that lacked any productive capacity without the guidance of her dominant left hemisphere. Could we be observing a collection of modular components without any sense of self or conscious experience of its capacities? To answer this question, a series of paired questions, one correctly answered positively and one negatively, were posed to each hemisphere in writing. Answers were lateralized and presented randomly to each hemisphere so V.J. never knew which hemisphere would have to answer the questions. She demonstrated accurate knowledge about herself and her family in both hemispheres. So, although the loss of communication between her hemispheres has handicapped her RH, it may maintain an independent sense of self. However, even though the motor programs for writing are in her RH, it has not been able to use them to express independent thoughts and desires to date. It would be easy to conclude that the RH of this patient only supported preconscious modules that participated in reading and writing only at the behest of the dominant LH prior to surgery. These preliminary re-

Stimulus	LVF / right hemisphere	RVF / left hemisphere

sults suggest this is a false picture of the isolated RH of V.J.; however, further studies are in progress to be certain whether this view can be correctly rejected.

Such behaviors indicate that RHs with varying language representation can exhibit goal-directed behavior and display the desire to cooperate with the experimenter to carry out experimental tasks. They demonstrate a variety of complex cognitive abilities that suggest the isolated RH is more than an automaton. Although these results have been obtained from some subjects

with minimal RH language, RHs without language remain mysterious. Without a code for communication, we remain unable to engage those RHs so that we can be certain we are observing their optimum responses.

Consciousness and the cognitive basis of reality

Study of split-brain patients over the past forty years has helped change our understanding of the nature of consciousness. The left-brain Interpreter seems to be the executive, coordinating entity that enables all of the

parts of a normal brain to interact with the environment in an integrated manner. But the status of the right brain continues to be a mystery. We can see some specialized capacities, hints of will and independence, but remain unable to positively characterize the RH or enlighten ourselves as to the experience of the world from the perspective of the RH. As we near the end of the Decade of the Brain, it appears George Bush may have been ahead of his time. It may be in the first decades of the 21st century that we see progress on the complex questions of human consciousness, will, and emotion built on the foundation of the more complete neurophysiological and neuropsychological understanding of brain function gained in this decade and on insights from the past.

In 1976, Rozin coined the term "cognitive unconscious" to describe the activity of the systems we have called "preconscious." Taking an evolutionary perspective, he suggested humans have evolved from creatures whose behavior was determined by modular systems with little integration. As these systems evolved and became more complex, consciousness emerged as a way of exerting executive control over diverse functions. One way of viewing the RH is as a less evolved entity with poor communication between modules, less sophisticated language, and debatable consciousness. Gazzaniga's (1983) view that a RH without language has cognitive skills that compare unfavorably with a chimpanzee may be consistent with such a view.

Perhaps we can re-invest the RH with some respectability by considering the evolutionary view of the implicit/explicit distinction proposed by Reber (1992). Reber does not find the arguments for modularity compelling, but he is sympathetic to the universality of the implicit/explicit distinction and suggests that implicit knowledge processes and explicit knowledge processes display similar phylogenetic and ontogenic development. Further, he suggests that implicit knowledge may provide a basis for the kind of "intelligent" behavior that IQ tests fail to measure. As with most cognitive dichotomies, this one probably does not lateralize clearly into the hemispheres. But it may characterize one of the relevant differences between them. The LH may play a greater role in the expression of explicit knowledge and the right may be more adept at shaping behavior based on implicit knowledge—hence the lack of effect of callosotomy on psychometric intelligence, anecdotal changes in post-operative initiative and behavior notwithstanding.

Finally, the best examples of behavior that appear to represent consciousness in the RH come from those split-brain patients with at least some language capacity. Our newest patient, V.J., is anomalous in that she controls written and spoken output with different hemispheres. She is also unique in another way. She is the

first split in my experience who is frequently dismayed by the independent performance of her right and left hands. She is discomfited by the fluent writing of her left hand to unseen stimuli and distressed by the inability of her right hand to write out words she can read out loud and spell. In the myriad articles discussing duality of consciousness, consciousness is sometimes considered as arising from the need for a single serial channel for motor output (Bradshaw, 1981; Güzeldere, Flanagan, and Hardcastle, this volume). In normally lateralized persons, the LH maintains control of output of both speech and writing. In V.J., we have two centers of control of the motor output of language, one partially disabled but still functional. One problem for this point of view is that some split-brain patients, notably J.W. and V.P., do have some control of motor speech from either hemisphere. However, in both of these cases, the control of spoken language developed after the surgical intervention, and this sequence of events may have different consequences for the conscious experience of it. If serial control of output is an important determinant of what we perceive as consciousness, and if the fluent shifting of control of output from one system to another is a part of that function, we may still have a good deal to learn from the split-brain model.
